The three methods therefore used in the modern operation are (1) diathermy coagulation, (2) electrolysis, (3) surface coagulation. The invention of new instruments and methods of applying them continues apace. Arruga especially has been fertile along these lines, devising tiny threaded plugs to close the trephine openings in cases of perforation of the choroid, lancets for orientation, and a retractor. The last is invaluable. Strampelli's "diathermophanoscope" embodies what is probably a useful idea. It is briefly, a transilluminator and diathermy handle all in one. Meesmann modified Coppez pyrometric electrode, by employing a fine pointed pyrometric electrode in a curved quartz tube with changeable point. Langdon uses the Shahan thermophore at a temperature of 65 degrees centigrade for 1 minute to produce surface coagulation. Gradle and Meyers (1938) and others have devised various electrodes particularly suitable for surgery around the macular area. The LaCarrière electrodiaphane, with which I am sure you are all familiar, has enjoyed a wide and justifiable reputation. The bent and beveled glass tube containing the platinum wire electrode permits the instrument to be applied beneath muscles and behind the globe. The bipolar electrolytic instrument introduced by Von Szily and Machemer in 1936 and described in detail in the *Traité d'Ophthalmologie* by Veil and Dollfus offers many advantages to the use of the usual electrodes. I do not know if they can be obtained in this country.

Each of the three methods of surgical treatment has its ardent advocates. The trend, however, is away from the exclusive use of a single method, and most surgeons are now using a combination of diathermy, electrolysis, and surface coagulation. As time goes on and reports come in, our knowledge will increase and one can readily foresee a standard operation evolved. Both Walker and Peter, for example, use electrolysis to supplement diathermy in the closing of small tears and to reduce to a minimum hemorrhage from retinal vessels. They use it in macular holes and to visualize the correctness of the location of the tear (ophthalmoscopic study). Diathermy puncture is now of two types, the juxtachoroidal and the perforating. The needles are becoming finer and shorter. Juxtachoroidal punctures are

used to isolate the tear by a barrage over the area of separation, the perforating punctures are used to attack the tear itself. The increasing tendency is to operate under the direct control of the ophthalmoscope. A few punctures are made and then the result noted with the ophthalmoscope; a few more punctures, then observation and so on. It therefore is obvious that drugs which will cloud the cornea should not be employed. Surface coagulation, according to Peter is indicated to create a sufficient number of points of choroiditic adhesive spots throughout the separated area.

To summarize briefly, the modern trend of the operation is as follows. The tear or hole is localized as accurately as possible and a surface mark placed on the sclera with diathermy. The localization is verified by transillumination either applied to the sclera and observed with the ophthalmoscope, or by shining the light from the ophthalmoscope through the pupil in the direction of the tear and noting a spot of light on the sclera. The hole is further localized by the insertion of an electrolysis needle or perforating diathermy needle and its appearance noted with the ophthalmoscope. The tear is then surrounded by perforating diathermy punctures, except in the macular area. The needles are introduced and left in place until the entire area of the separation has been treated by surface coagulation and electrolysis, or juxta choroidal diathermy punctures. Some surgeons (Peter) prefer to cover the entire area with negative galvanic needles ($\frac{3}{8}$ to $\frac{1}{4}$ mm.) of perforation, and in addition use catheters freely in the region of the tears. I am inclined to agree with Weve, however, that it is unnecessary to do more than seal off the tear. Insertion of pins over the entire area of the separation except where there is not a hole found is, to my mind, unnecessary mutilation.

It is perhaps pertinent to mention here another operation which may be found to be useful in cases not suitable for the above operations. I refer to the sclerectomy of Mueller modified by Lindner under the term of eyeball shortening operation. This operation is described and illustrated by Paschel and Miller who report a successful outcome in what otherwise probably would have been a hopeless case. It consists of an elliptic excision of a piece of sclera over the detached area, great care being taken not to injure the choroid. A case of retinal detachment associated with a scleral ectasia was successfully

treated by me. The entire staphyloma was excised more or less according to Mueller's technique. I am convinced that no other operation would have succeeded in this case.

Anesthesia. Local anesthesia is unsatisfactory. It should be used only when other methods are contra indicated. Avertin anesthesia is the one of choice if it can be safely used. Its advantages are (1) perfect anesthesia (2) a free field for operating unhindered by the anesthetist, (3) slight danger of postoperative nausea, (4) no disturbance of the conjunctiva and cornea as is caused by local anesthesia, (5) no risk such as is encountered in gas-ether in the presence of diathermy current. If avertin cannot be used, ether may be fairly safe if a wet towel is so placed as to prevent ether fumes from reaching the field of operation.

Post operative and convalescent care of the patient. How long one should keep a patient absolutely quiet in bed with eyes blindfolded is a debated question. The loch brille or pin hole glass of Lindner is indispensable to help keep the eye fixed when the bandages are removed. Another method is that of Arruga, who sews the lower lid to the eyeball with a suture through the inferior rectus. There can be no hard and fast rule since the healing process varies with each case. It is considered wise to keep the patient as quiet as possible in the hospital until the puncture points have started to become pigmented, a condition which varies from 2 to 5 weeks, sometimes longer. It can thus be seen how important is frequent postoperative ophthalmoscopic examinations.

TUMORS OF THE UPPER JAW

Particularly Tumors Related to the Sinuses

CARL W WALDRON, M D, D D S, F A C S, Minneapolis, Minnesota

THE upper jaw is subject to the development of practically all of the tumors that involve bony tissue and in addition may be the site of origin of cystic and calcified tumors of the odontome group. Furthermore, it may be invaded by tumors originating within the accessory nasal sinuses or by tumors of adjacent tissues within the oral cavity or nose. Malignancies of the upper jaw and sinuses have been studied and reported upon at great length so it will be my purpose to discuss more particularly the diagnosis and treatment of the more common benign tumors and certain unusual tumors involving this region that are of interest to the otorhinolaryngologist.

ODONTOMES

These tumors arise from the cells that are concerned with tooth development and may be conveniently classified as follows¹

I Epithelial odontomes Tumors in which the abnormal development takes place in the dental epithelium

1 *Dental or root cysts* These develop at the root ends of teeth that have erupted. Pulpal and root end infection, and pulp death of traumatic or chemical origin are apparently the irritative factors in their development. They may occur at the root ends of deciduous teeth. They may also develop in an epithelated granuloma left in the alveolar process at the time of extraction of an infected tooth.

A *Indeterminate type dental cysts* occur in any portion of the jaw. They are frequent in the region of the angle or ascending ramus and may be multiple. They are not attached to the root of a tooth infected or otherwise, nor will there be a history of the extraction of such a tooth. They also occur in regions where supernumerary teeth are most frequently found and may be due to supernumerary anlagen.

2 *Dentigerous or follicular cysts* In these cysts, the wall embraces not a root but the crown of a completely or partially formed unerupted and usually misplaced tooth. Some of these cysts contain cells typical of the adamantinoma.

3 *Adamantinoma or multilocular cysts* These tumors show columns or masses of epithelial cells

From the Division of Oral Surgery, University of Minnesota.
Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 21-25, 1940.
¹This classification is a modification of the British Dental Association classification.

of the enamel organ types—ameloblasts-cuboidal cells, and stellate reticulum. They may be found and operated upon in an early stage when they are not clinically cystic, but rather of a solid consistency. Microscopic examination, however, nearly always shows cell degeneration and beginning cyst formation of the epithelial masses. The term "epithelioma" should not be employed in the consideration of these tumors.

II *Composite odontomes* Tumors in which the abnormal development takes place primarily in the dental epithelium, and secondarily in the dental papilla, and may occur in the follicle also.

1 The abnormal development of the dental epithelium is such that the formation of numerous irregular dentine papillae results, and are calcified in one mass or sporadically.

A *Complex composite odontomes* When tooth structure is shown in the microscopic section and not in the gross specimen which appears like an irregular mass of bone.

B *Compound composite odontomes* A large number of tooth elements are present. They may be fused or be separate within a cyst cavity.

2 The abnormal development of the dental epithelium is such that the formation of two or more tooth like dentine papillae results and are calcified as one mass.

A *Germinal composite odontomes* Present fusion of teeth combined with malformation, such as masses of dentine and cementum.

B *Gestant composite odontomes* One tooth develops within another.

C *Enamel nodules or enamel pearls* The abnormal development of the dental epithelium is such that the formation of a dilated portion of the dentine papilla results and is calcified as one mass.

A *Dilated composite odontomes*
a Fusiform type presents a widely dilated or hollowed-out foot with a normal or semiconical crown.
b Coronary type presents dilatations and malformations of the crown portion of the tooth.
c Radicular type presents irregular calcified masses of dentine and cementum projecting from one surface of the root.

III *Connective tissue odontomes* The abnormal development takes place in the dental tissues of mesodermic origin alone. (The dental follicle.)
1 *Cementomes* Consist of solid irregular masses of cementum (1) that may develop about the roots or crown of a tooth that eventually erupts after which the cementum may continue to enlarge or (2) may surround and destroy an unerupted

immature tooth. These masses enlarge and expand the alveolar plates.
Fibrous odontomas. Apparently the same type of tumor as central fibromas (benign osteogenic tumors), and the fibromas that develop from nerve sheaths. The diagnosis of fibrous odontoma is presumed when the tumor is associated with an unerupted malformed tooth or other dental anomaly.

This classification, based on a very extended study by a committee of the British Dental Association, is to my mind most practical for the surgeon called upon to treat these conditions. Other classifications that have been proposed by pathologists tend to confuse rather than help the surgeon in the diagnosis and treatment of the individual patient. For instance, in many texts, dental root cysts (radicular cysts) are considered to be an inflammatory cyst and not a cystic tumor. While these are from the standpoint of etiology associated with root end infection, traumatic or chemical pulp death or residual alveolar process infection, their clinical course in so far as the destruction of bony tissue and the involvement of the sinuses is concerned, cannot be differentiated from that of the dentigerous cyst. Furthermore, the microscopic examination of cyst walls of both types fails to reveal any diagnostic features that differentiate the cyst wall of the dental root cyst from that of the dentigerous cyst. It is a well known fact that examinations of serial sections of the walls of dentigerous cysts show that some of them are at least potentially *adamantinomas*. These findings convince me that these cystic tumors should be classified in one group as epithelial odontomes and not considered separately, sometimes even in separate chapters as is the case in some textbooks. Consequently the dentigerous cysts of the maxilla present potential problems from a tumor standpoint that must be kept in mind in the consideration of the operative techniques designed to prevent the development of persistent fistulas between the mouth and the maxillary sinus or the floor of the nose by leaving in the major portion of the cyst wall.

Cystic odontomes of the dental root and dentigerous types may develop in the anterior the lateral, or posterior portions of the maxilla. As already noted, their clinical manifestations, growth, and effect upon the bony substance of the upper jaw and encroachment upon the sinuses are quite similar. The rate of enlargement of a cyst varies considerably and is difficult to determine as most patients are operated upon soon after the discovery of the presence of a cyst. Occasionally one can locate a roentgenogram taken

some years previously, showing beginning cyst formation that was either not diagnosed or was neglected. In the case of dental root cysts, one may at times estimate the duration of the cyst by the date of a severe dental traumatism, the devitalization of a tooth or the insertion of a synthetic porcelain filling. These cysts may be found at any age, although dentigerous cysts are more common during the period of the development and eruption of the permanent teeth. The direction of the extension of the cyst varies considerably. They may grow more or less equally in all directions or may extend largely in one direction. They tend to project on the labial or buccal surface of upper jaw presenting as a more or less rounded prominence. This may be soft, hard, or compressible with crepitation, depending upon the amount of loss of the overlying bone due to resorption of the alveolar plate brought about by the presence of the enlarging cyst or the presence of newly formed bone overlying the cyst wall.

These findings may also be present and demonstrable in the hard palate or the cysts may extend upward to elevate the floor of the nose to a considerable degree or may obliterate the entire maxillary sinus and even extend farther without any buccal or palatal evidences of extensive cyst formation. Cysts may expand and thin out the overlying tissues to rupture or they may be excised on suspicion of an abscess formation following which there may ensue a very low grade secondary infection. The cyst contents vary markedly in consistency and color—depending upon the types of degenerative processes affecting the epithelial and connective tissue of the cyst walls together with the character of the exudates or presence of hemorrhage modified at times by low grade infection. Very rarely an extremely acute infection may for no apparent reason involve a cyst that has been developing for months or years without producing any symptoms. Discharging sinuses and infections of a cyst in the maxillary sinus region are often confusing in the matter of correct diagnosis and treatment.

Diagnosis. Careful clinical examination of the oral region together with rhinoscopic examination may establish a presumptive diagnosis of the presence of a cystic odontome. If permanent teeth are missing with no history of their extraction, the presence of a dentigerous cyst should be suspected. Roentgenographic examination is essential to determine the position and extent of the tumor, the presence of unerupted teeth, etc.

Regular intra-oral dental films are useful but occlusal films of larger No. 3 size, $2\frac{1}{4}$ by 3 inches, taken in the anterior and the oblique lateral pro-

to function normally for many years, provided the root ends are not exposed by the surgical removal of the cyst membrane. Pre-operative dental x-ray films will usually show the intimate relationship of the cyst wall to the underlying root ends and will determine the necessity of leaving the cyst wall to protect the vitality of the teeth. In more recent cases, I have left this lower portion of the cyst wall undisturbed with uniformly good results in so far as the healing of the maxillary sinus cystic cavity is concerned.

Another problem that warrants detailed discussion is that of the treatment of large cysts that not only obliterate the maxillary sinus, but also extend under the floor of the nose sometimes past the midline beneath the floor of the nose on the opposite side. If a Partsch operation is performed the postoperative course may extend over months or a year or more. If a Caldwell-Luc cyst procedure is undertaken the cystic area beneath the floor of the nose constitutes a pocket where exudates may collect, become foul smelling, and give the patient no end of annoyance and discomfort. To prevent this postoperative condition, a two stage procedure has been undertaken with gratifying results. The first procedure is a Partsch operation exposing the anterior extension of the cyst cavity but not uncovering it completely on its labial aspect. It is then treated after operation in a routine manner by gauze packing two or three times a week until the anterior extension of the cyst has filled in sufficiently to obliterate that portion of the cavity that was present beneath the floor of the nose. This may take 3 or 4 months to accomplish after which, the Caldwell-Luc cyst procedure may be undertaken and the oral incision that had remained open since the first operation is closed by undermining and suturing. The comfortable and satisfactory end-results have fully justified the time and care spent on several cases that have been treated in two stages in this manner. The prolonged period of dressings and the greater or lesser deformities that have been avoided amply repay the patient for the confidence and co-operation shown in accepting two operative procedures in order to obtain a more satisfactory ultimate result.

In case a portion of dentigerous cyst wall is left in position to prevent fistula formation or to shorten the postoperative course as already outlined, it is essential to have a microscopic examination made of that part of the cyst wall removed with the window. Any thickened or projecting portion of the cyst wall should also be excised and examined to be sure that the epithelial cells are not of the adamantinoma type. Such a condition

is found very rarely but must be kept in mind and, if present, excision of the entire cyst wall or cauterization by diathermy should be employed.

Should permanent fistulas develop to communicate with the nose or maxillary sinus, carefully made dental restorations will largely overcome the discomfort incident to such perforations.

Atypical cystic tumors of the maxilla that involve the maxillary sinuses have come under our observation several times. They have presented combinations of cystic areas and masses of fibrous tissue and bone in association with unerupted malformed teeth. The exact diagnosis may be somewhat obscure but is likely to be a variant of a composite or fibrous odontoma or an atypical osteitis fibrosa cystica—but microscopic examination will establish the benign character of the tumor tissue. The treatment is in general accordance with that already outlined for cystic odontomas depending largely upon the position and extent of the tumor.

The adamantinoma of the maxilla is very slow growing with insidious onset and consequently presents considerable difficulty in the matter of early diagnosis. Symptoms may be practically absent or there may be merely an indefinite feeling of pressure or tension. Slight neuralgic pains or tenderness referred to the maxillary sinus area may be noticed by the patient. In other cases, the symptoms are localized to the teeth and alveolar process and are likewise ill defined. This tumor may be present for many years before any definite enlargement of the maxilla may be demonstrated. Dental roentgenograms tend to be inconclusive and routine sinus films may show but slight or moderate clouding of the maxillary sinus.

These considerations account for the difficulties in diagnosis and the delay in instituting adequate treatment for this tumor. Months and years of valuable time may be lost while the patient is undergoing dental treatment or repeated punctures and irrigations of the maxillary sinus. Intranasal window operations may be performed to improve sinus drainage without the removal of tumor tissue for biopsy and thus more time may be lost. I have seen several patients whose histories suggested the presence of an adamantinoma for many years before the diagnosis was established.

I hesitate to bring into this discussion such a controversial subject as the relative merits of the intranasal antrum operations versus the canine fossa approach to the sinus used in the Caldwell-Luc procedure in the treatment of chronic maxillary sinusitis, realizing that men who employ

Fig 1 Two stage operative procedures for cystic tumors that obliterate the maxillary sinus and extend beneath the floor of the nose Stage I Partsch operation by means of a buccal window through which the cyst

cavity is dressed Stage II 3 to 6 months later as soon as the cavity beneath the floor of the nose has become obliterated A, Intranasal window established and surgical closure of the operative approach used in Stage I

the Caldwell-Luc procedure are greatly in the minority While I concede that in the hands of skilled rhinologists the intranasal procedures are effective and satisfactory in every particular, I do feel that the buccal approach to the maxillary sinus gives better access to, and more complete visualization of, the operative field, thus affording more thorough and accurate surgical treatment of the condition present

In my experience there have been no disadvantages associated with the Caldwell-Luc procedure other than swelling of the cheek that lasts but a few days I am sure that rhinologists who employ the Caldwell-Luc procedure will quickly develop a diagnostic sense that will differentiate between the varied appearances of chronic inflammation of the sinus mucosa on the one hand and the more serious tumors and the malignant tumors on the other hand

For this reason, I would urge that rhinologists employ the Caldwell-Luc procedure much more frequently especially in cases with obscure symptoms in order to make possible the earlier diagnosis of tumors of the sinus and to avoid the humiliation incident to prolonged sinus treatments in tumor cases

The nature of the tumor cannot be diagnosed by visual examination alone and biopsy is necessary to determine the treatment to be instituted

Adamantinomas of the maxilla and sinuses must be considered as serious tumors that may endanger the life of the patient on account of inoperable extensions or the onset of meningitis due to the extensions of the growth and secondary infection The prognosis varies with the position and extent of the tumor and the greater or lesser degree of histological activity of the tumor cells The more or less favorable position of the tumor

is a large factor in its curability, and it is obvious that the inferior anterior location affords a much more favorable prognosis than does a location extending posteriorly and superiorly This corresponds with the conclusions of Ohngren who divides tumors of the upper jaw and antrum into two groups by a plane which passes from the inner canthus in a direction backward and downward to the angles of the mandible It must be remembered that an unsatisfactorily prepared and stained frozen section may present difficulties in diagnosing adamantinomas from adenocarcinoma and at times it may be wise to postpone the destruction of the tumor by cauterization or with surgical diathermy until the day following the biopsy This will permit the preparation of a well stained permanent section making accurate diagnosis and the determination of the degree of cell activity less difficult

Adamantinomas must be completely removed and destroyed in order to prevent recurrence Surgical diathermy is the method of choice and should be employed in a thorough and painstaking manner The bony wall surrounding the tumor tissue should be cauterized thoroughly in every portion of its surfaces and any regions in which the tumor may have extended through the antral walls to the soft tissues should be carefully treated with a protected endotherm point The same meticulous care should be employed in destroying the tumor tissue that may have extended into the ethmoidal sinuses These tumors are resistant to radiation, although radium may be employed with apparent success in regions that are inaccessible to adequate treatment by diathermy Extensions of adamantinomas beneath the orbit may produce orbital displacements, exophthalmos, and a variety of inflammatory conditions of the

orbit and globe. It may be occasionally necessary to remove the eye but usually the displacement or inflammatory reaction subsides as soon as healing is complete. The postoperative course may be stormy and painful until sequestra have become separated and are removed, particularly when orbital signs and symptoms were present before the operation. Usually from 6 weeks to 3 months or more elapse before it may be determined that the margins of the necrotic bone may be pried loose and the sequestra can be removed. Healing thereafter is usually without incident and the region becomes comfortable. Examination should be made from time to time in order to be sure that all parts of the original tumor area are well healed and firmly epithelialized.

Recurrences of this tumor are due to failure to remove and destroy all tumor tissue. Such recurrences are usually of very slow growth and prognosis is still usually favorable except when situated in the posterior superior regions. It is not wise to attempt a plastic closure of the buccal opening into the operative area for 2 or 3 years, until one is satisfied that there are no evidences of recurrences—an obturator may be made or the patient may use cotton or gauze to plug the opening at meal times.

Composite (calcified) odontomes may involve the maxilla. These are sometimes associated with areas showing fibrous or cyst formations. Diagnosis is usually not difficult, as roentgenograms usually reveal the nature of the tumor. These tumors are essentially benign and do not endanger life. They do, however, show a tendency to develop acute infections in the tissues adjacent to the surface of the tumor and produce a cellulitis with abscess formation. Occasionally this may occur without any previous knowledge of the presence of a calcified tumor. Several weeks should elapse following such an infection before any attempt is made to remove the tumor.

The treatment is surgical excision of the entire tumor mass and the operative approach is much the same as for the cystic odontomes. Excision of the calcified tumor may be difficult, requiring painstaking removal of overlying and adjacent bone by means of chisels or burrs in order to make possible the delivery of the tumor from its bed. The resulting defect may present quite a problem on account of an extensive exposure of the sinuses and nose together with loss of the alveolar process ridge. The operative approach is from the buccal or the incision may be made along the alveolar process ridge. A coperiosteal flaps may be retracted palatally and buccally to provide a wide exposure of the tumor area and may at the con-

clusion of the operation be sutured to close off the operative field from the mouth if conditions permit. These tumors are not likely to extend beneath the floor of the nose and the sinus tumor cavity may be made to communicate with the nose by means of a naso-antral window to thus shorten the postoperative course as outlined in the discussion of the treatment of cystic odontomes.

Fibrous odontomes or central fibromas of the maxilla can rarely be diagnosed before operation, as the x ray appearances are similar to those of the cystic odontomes. Fibromas are rare and biopsy is necessary in order to complete the diagnosis. The treatment is complete excision and the operative and postoperative treatment corresponds with that of the cystic odontomes in which the entire cyst wall is removed.

Cementomas develop slowly but may attain a considerable size to encroach upon the maxillary sinus. The x ray appearance of these tumors is similar to the composite odontomes and the operative and postoperative treatment is essentially similar in every respect.

As already noted in the introduction to this discussion the upper jaw may be the site of any of the tumors that involve bone. These may be classified according to the various modifications of the Codman registry nomenclature of the American College of Surgeons.

- I. Metastatic tumors of the jaw are rare. Metastases of carcinoma from the breast, thyroid, prostate, ovary etc. are on record. Sarcoma and hypernephroma metastasizing to the jaws has been reported.
- II Periapical fibrosarcoma is less malignant form of sarcoma that has been found lying next to the base of the jaws. It arises in the outer layers of the periosteum or in the adjacent fascia or tendinous insertions. It does not invade the bone but may cause pressure absorption. It does not form osteoid tissue, cartilage, or bone. Metastases infrequently occurs.
- III Osteogenic tumors are derived from cells concerned in the development of bone and cartilage, etc.

A. Benign osteogenic tumors

Hyperostoses are inflammatory enlargements of a diffuse type that frequently involve the malar region and tuberosity of the maxilla. Leontias ossea is of this type. Exostoses may occur on the lingual surface of the mandible and in the center of the hard palate, torus palatines. They have been noted to occur frequently in the tuberculous.

3. Osteomas may develop in any portion of the mandible or maxilla. When developing in the region of the condyle, the ascending ramus is lengthened, causing opening of the bite. In the upper jaw the maxillary sinus, nose, or orbit may be involved. The other facial bones may develop these tumors.

WALDRON TUMORS OF THE UPPER JAW

509

- 4 Fibromas may occur as central tumors or in the deeper layers of the periosteum
- 5 Chondromas may develop centrally or from the alveolar margins, the palate, the coronoid, or the condylar cartilage. Pure chondromas of the jaw are rare. Tumors of this group may show combinations of cartilage, fibrous tissue and bone

B Malignant osteogenic tumors. Osteogenic sarcomas may arise in the central portions of the jaw and in the deeper layers of the periosteum or may arise alone from the subperiosteal layer. It is often difficult to determine the exact site or origin, particularly in the maxilla where such tumors may start in the subperiosteal layer of the maxillary sinus membrane. Types

- 1 Those destroying bone—osteolytic
- 2 Those forming bone—sclerosing
- 3 Those forming cartilage—chondrosarcoma

IV Inflammatory conditions that may simulate tumors of the mandible and maxilla

A Osteoperiostitis (osteomyelitis) occurring in atypical forms may occasionally simulate a primary tumor of the mandible or maxilla

- 1 Traumatic periostitis may occur in chronic form without an acute onset. Hemorrhage and resulting repair, cartilage, and bone formation may closely simulate tumor for a few months' observation will clear up the diagnosis
- 2 Syphilitic periostitis or osteoperiostitis occurring in the second or third stages of lues may resemble a sarcoma
- 3 Infectious osteoperiostitis—osteomyelitis

a. Pyogenic infection of a low grade type may produce tumefaction that necessitates observation over a period of time in order to rule out tumor formation

b. Tuberculous periostitis and osteitis may for a considerable time simulate tumor formation

B Actinomycosis of the tissues surrounding the mandible, particularly when hard, may for a time simulate sarcomas. The bony substance of the jaw is rarely if ever involved and the contour of the mandible will be seen to be normal in the roentgenogram.

C Osteitis fibrosa cystica occurs frequently in the mandible and maxilla. It is characterized by cystic areas without an epithelial lining, fibrosis, condensing osteitis. Other bones may also be involved. This condition may be associated with parathyroid tumors and disturbances in the calcium phosphorus balance

V Central giant cell tumors are identical in structure to the giant cell epulides. They develop centrally and expand the jaw until the cortex is reduced to a thin shell or becomes destroyed. They are usually soft and red and present a varying number of multinucleated giant cells in a loosely woven connective tissue stroma

VI Angiomas, benign or malignant, of the bony substance of the jaws are very rare, but have been recorded

VII Ewing's sarcoma, endothelioma, may develop in the mandible in several areas simultaneously, destroying the bone. The tumor consists of small, polyhedral cells with no intercellular substance. Fever, pain and the x ray appearance may simulate osteoperiostitis—osteomyelitis

VIII Myelomas may involve the mandible and skull along with other bones. The myelitic substance of the bone is destroyed by the tumor cells. Albumosuria is present.

Metastatic tumors of the maxilla are rare and usually insidious in their course, presenting difficulties in diagnosis except by biopsy. The prognosis depends upon the type of tumor, its degree of malignancy and the prognosis of the primary tumor. Many of course are inoperable on this account. Metastases to the jaws of carcinoma of the breast, thyroid, prostate, and ovary have been reported as well as sarcomas and hypernephromas. A benign tumor of the thyroid metastasizing to the mandible has been reported by Ivy

Periosteal fibrosarcoma arising on the external surface of the maxilla may necessitate the exposure of the maxillary sinus in its removal by excision

Osteogenic tumors of the maxilla may be benign or extremely malignant osteogenic sarcomas. The benign tumors are the hyperostoses, exostoses, osteomas, chondromas, and fibromas.

Hyperostosis may produce a massive enlargement of the molar region and tuberosity. The buccal and palatal aspects are more particularly involved although the tumor may extend upward to encroach upon the maxillary sinus. Removal of the excess bone by chisels and curets to restore a normal contour gives satisfactory results in that production of new bone ceases. Should the maxillary sinus be exposed in the surgical procedure, it usually does not require any special treatment, as the mucoperiosteal incisions may be sutured

Central osteomas, fibromas, and chondromas may also encroach upon the maxillary sinus, and their surgical removal may produce large openings into the sinus cavity. These may usually be closed by suturing. Occasionally it may be wise to make an antrobasal window through which postoperative treatment may be carried out

Osteogenic sarcomas of the maxilla are relatively infrequent—about 10 per cent of the primary and secondary malignant tumors involving the maxillary sinus will, on microscopic examination, be found to be osteogenic sarcomas presenting wide variations of sarcomatous cellular detail which accounts for the fact that these tumors have been designated as spindle cell sarcoma, round cell, myxosarcoma, osteosarcoma, chondrosarcoma, mixed, angiosarcoma, or combinations of several types. These tumors may arise in the deeper layers of the periosteum or beneath the periosteum in the cortical or medullary portions of the alveolar process or body of the maxilla. In these cases the early symptoms may be merely

obscure dental pain or loosening of teeth, which progresses to an apparent tooth or jaw infection with suppuration and necrosis. On the other hand, the tumors may arise from the periosteum of the maxillary sinus and may grow to fill the antrum before producing definite symptoms of tumor formation. Local ulceration of the tumor within the sinus may lead to symptoms of nasal and sinus infection such as obstruction or discharge of a purulent or blood stained nature. Later nasal polyps may be seen on examination and bleeding from the nose may become frequent. The condition may be erroneously diagnosed as a chronic infection of the maxillary sinus and much valuable time is thereby lost. Continuing to grow the tumor may perforate the bony walls and extend into the cheek the orbit, the nose, or the palate.

Enlargement of the cheek of recent origin in a middle aged person is usually malignant if not of inflammatory dental origin and should not be neglected. At times, displacement of the eye may be noticed a few weeks after the onset of nasal symptoms. Early diagnosis is most essential in order to make possible adequate treatment of this extremely malignant tumor. Persistent facial pain aggravated by lying down increasing nasal obstruction of short duration, lacrmal duct obstruction, mucoid or suppurative nasal discharge particularly if blood stained, are symptoms that should be considered due to a malignant tumor until the condition has been proved to be inflammatory or benign. Roentgenograms should be made, using the standard and special projections to show the maxilla and the sinuses. Careful examinations of the films should be made to determine the presence of defects of the bony walls, which almost invariably indicate destruction by tumor formation. I have seen but one patient in which such a defect proved to be due solely to chronic inflammation.

These symptoms and examination findings should convince the surgeon that the condition is a malignant tumor and he should plan the treatment accordingly. At operation, a frozen section should be made to determine the diagnosis and the degree of malignancy.

The treatment of osteogenic sarcomas of the maxilla is destruction by diathermy supplemented by radiation therapy preferably by means of radium emanation or element from within the tumor and sinus area (5). An interval of time between the biopsy and the destruction of the tumor tends to increase the operative difficulties and should be avoided. Intratracheal nitrous oxide is the anesthetic of choice and the operative ap-

proach is either through the mouth or by means of a lateral rhinotomy depending upon the position of the tumor. Primary and secondary bleeding is controlled by packing. If persistent, the ligation of the external carotid artery may be come necessary.

This discussion of osteogenic tumors of the maxilla holds true for squamous cell epitheliomas and adenocarcinomas which are much more frequent—about 70 per cent of all primary and secondary malignant tumors of the antrum.

The postoperative course is much the same as has been described in the case of adamantinomas of the maxilla and antrum. Any defects and loss of tissue of the maxilla or cheek may be reasonably well restored by plastic surgery. This should not be undertaken for several years, until danger of tumor recurrence is apparently well past. Dental restorations of the obturator denture type may be necessary to close off the antrum or nose from the oral cavity.

As to chondrosarcoma of the maxilla, Phe-mister is of the opinion that the term osteogenic sarcoma is used too broadly at present and is of the opinion the malignant cartilaginous tumors may be recognized as a class by themselves and so designated. He reports a case of chondrosarcoma of the maxilla that terminated fatally after two recurrences with metastasis. The microscopic examination showed hyaline cartilage with extremely little calcification or ossification. This tumor filled the antrum to bulge above the gum margin. The recurrences extended through to the nasopharynx, orbit, and the nose.

Osteitis fibrosa cystica is a borderline inflammatory tumor that may involve the maxilla to produce a slowly progressing enlargement of the upper jaw. The overlying soft tissues and the periosteum are apparently not involved by the growing tumor. The molar region and the tuberosity are common sites for the development of this condition and consequently the maxillary sinus may be more or less obliterated by the gradual extension of the process in the upward direction. Symptoms are usually obscure—often limited to a feeling of pressure slight pain, or recurring neuritis. Later the patient is conscious of an enlargement of the jaw or cheek. These growths may be associated with similar lesions in the long bones and parathyroid tumor or with disturbances in the calcium phosphorus balance. Occurring in the region of the antrum these tumors are of considerable interest to the rhinologist. Some of these growths present multiple cysts readily recognized in the roentgenogram, whereas others show but massive enlargement of finely trabecu-

CHONDROMA TUMORS OF THE UPPER JAW

ated bone similar to hyperostosis. Treatment is not standardized for this condition. Careful examination should be made to rule out parathyroid tumor. Surgical treatment is usually limited to the removal of enough tumor tissue to correct the enlargement and deformity. These growths tend to be self-limiting and regressive and the postoperative course is usually without incident. Adequate mineral and vitamin therapy is a useful adjunct to surgical treatment in the management of these tumors.

Giant cell tumors of the maxilla occur in two forms (1) the giant cell epulis, and (2) the central giant cell tumor. The epulis develops in the region of the gum margin but may extend deeply into the body of the maxilla. The central giant cell tumor tends to grow in all directions to involve the maxillary sinus and also protrude on the buccal and palatal aspects of the upper jaw. These tumors may be indolent and slow growing with relatively feeble invasive and destructive qualities or an active malicious growth which increases rapidly in size to destroy the overlying bone and extend into the adjacent soft tissues. The microscopic examination shows large numbers of giant cells in a stroma of actively growing cells of both round and spindle type. Giant cell tumors have been studied extensively with reference to their etiology, pathology, and the relationship of these tumors to solitary bone cysts and osteitis fibrosa cystica. Some authorities favor radiation therapy rather than surgical removal by curettage and cauterization. Others stress the fact that many of these tumors are not radiosensitive and when so treated valuable time is lost and subsequent surgical treatment is of necessity more radical and mutilating. Surgical treatment is the method of choice in giant cell tumors of the maxilla. Removal of the tumor tissue by enucleation and curettage of the bony cavity followed by cauterization is effective in eradicating this tumor. The operative defect will determine the nature of the postoperative treatment and the handling of the problem of sinus exposures in a similar manner to what has already been discussed.

Squamous cell epitheliomas are by far the most common primary and secondary malignant tumors of the maxillary sinus. Adenocarcinoma occurs about as frequently as the various sarcomas that may be grouped as osteogenic tumors. The

symptoms are about the same as those noted in cases of adamantinoma and osteogenic sarcoma and the treatment is essentially electrosurgical and by radiation therapy rather than by the radical surgical procedures in vogue two decades ago.

The degree of malignancy as shown in the microscopic section will determine the technique of treatment. Tumors of lesser malignancy require careful and painstaking destruction of the entire tumor by surgical diathermy and when bone is involved the periosteum is likewise treated to prevent recurrence. Great care must be taken to avoid leaving any tumor tissue in any region, and frozen sections may be made of any suspicious areas. Further destruction by diathermy may be instituted and radium seeds inserted. Highly malignant tumors should be explored and thoroughly coagulated centrally to provide adequate drainage and to produce a cavity large enough to permit the insertion of radium element and radium emanations may be implanted around the periphery of the growth. The postoperative considerations and course have already been discussed under adamantinomas and osteogenic tumors.

NEUROSURGICAL ASPECTS OF FACIAL INJURY

HARRY HYLAND KERR, M.D. C.M. F.A.C.S., Washington, D.C.

GROSS injury of the nerve supply of the face is comparatively rare in trauma of this region. This is the more surprising when we recall the rich and complicated nerve supply of the head. Nearly all of the twelve cranial nerves are distributed in this region, including the nerves of special sense—smell, sight, taste, and hearing. Tactile sensibility is transmitted through the fifth cranial nerve by three great branches leaving the base of the skull through three separate foramina of exit. The facial muscles are innervated by the seventh cranial nerve that leaves the cranial cavity through a tortuous bony canal in the petrous portion of the temporal bone.

That this rich nerve supply should escape injury is explained by certain embryological and anatomical factors. The base of the skull, it will be remembered, is embedded in cartilage, and becomes ossified comparatively early in life. The base of the skull becomes a massive block of cancellous bone whose otherwise cumbersome weight and size are relieved by numerous cavities lined by mucous membrane and connected with the nose, the paranasal sinuses.

Trauma severe enough to fracture this basilar block of bone produces only fissures unless it is of such severity that the skull is crushed when death immediately ensues. Though fissure fracture of the base of the skull may cause grave consequences from resulting intracranial hemorrhage, it is only when the fracturing fissure passes through, or in the neighborhood of one of the many foramina of exit of the cranial nerves that injury to these structures takes place.

As there is little or no displacement of bone fragments in fractures of the base of the skull, the fractures themselves are disregarded and our attention is centered on the complications—hemorrhage, edema, or nerve injury.

The characteristic reparative process of the bones of the skull is of great surgical importance. The massive temporary callus following fractures elsewhere in the body is not seen. Permanent repair of fracture of the skull is also accompanied by a minimum of permanent callus. Thus no bony masses mark the site of repair and the line of fracture returns almost to its normal configuration.

Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 3, 1940.

This fortuitous phenomenon prevents these fractures from either encroaching on the cavity of the skull proper or on the foramina of exit of the cranial nerves. If compression of a nerve occurs from hemorrhage immediately following injury we may expect the compression to subside promptly with absorption of the clot. We also expect no permanent interference in the function of the nerve from resulting callus formation or exostosis.

Therefore, the dysfunction of the cranial nerves following trauma of the head is usually transient paralysis. Unless the particular nerve is actually severed or crushed by the injury its function returns in a comparatively short time.

Certain nerves seem to be more easily hurt than others. This is probably best explained by the narrowness of their foramina of exit, which permits minimal displacement or hemorrhage to disturb the delicate axon cylinders without gross injury of the nerve trunks themselves. The sixth cranial nerve supplying the external rectus muscle of the eye is the most commonly hurt. Hence a transient extra-ocular palsy with diplopia is not uncommon in cases of fracture of the base of the skull. Injury of the other cranial nerves supplying the eyeball and its extra-ocular musculature is much more rare.

In third nerve injury the greatest permanent disability is ptosis of the eyelid because of the deformity produced. Anchoring the lagging eyelid to the frontalis muscle by a fascial band is the best treatment for this defect. The eyelid is elevated to a more normal position and can be raised by contraction of the ipsilateral frontalis muscle.

The next most commonly affected cranial nerve to be injured in fracture of the base of the skull is the seventh, or facial, nerve. Since it supplies all of the muscles of the face, its injury produces marked disfigurement and disability.

A total paralysis of the facial nerve produces complete relaxation of the corresponding side of the face. The patient is unable to close the eye, with resulting danger to that organ. Because the mouth cannot be closed on the affected side, there is constant dribbling of saliva and marked interference with mastication. Even a partial facial palsy is disfiguring. As expressional movements are principally affected, the sufferer feels the embarrassment acutely and begs for relief.

Fig 2

Fig 3

Fig 4

Fig 1 Case 2 Complete dehiscence of the left seventh nerve repaired by 15 millimeter graft from the anterior cutaneous femoral nerve Before operation Face in repose

Fig 2 Case 2 Before operation Patient smiling

Fig 3 Case 2 After operation Face in repose

Fig 4 Case 2 After operation Patient smiling and closing the eye

Fortunately, surgery has something to offer these patients. The deformity of the face may be improved by the insertion of fascial bands in the subcutaneous tissues. These are attached to the angle of the mouth, the nasolabial fold, and to the upper and lower eyelids, and are anchored in the temporal fascia. Such an operation restores the facial symmetry and prevents overstretching of the affected muscles. It is a great relief to these unfortunates, but, of course, does not restore the function to the paralyzed muscles.

Re-innervation of the affected musculature may be accomplished by direct repair of the divided nerve, or by anastomosing a neighboring motor nerve with the distal portion of the paralyzed nerve. The latter operation has enjoyed a good deal of popularity since it was first done by Sir Charles Ballance in 1895.

He divided the spinal accessory nerve in the apex of the posterior triangle of the neck and anastomosed its proximal segment to the distal segment of the freshly divided facial nerve. Later Ballance suggested the use of the hypoglossal nerve. This operation, I believe, is now the more popular procedure since the accompanying movements of the tongue are less disfiguring and disabling than the movements of the shoulder that accompany spinal accessory facial anastomosis.

The results of these procedures, as satisfactory as they sometimes are, do not compare with the results accomplished by direct nerve suture or even to nerve graft of the seventh nerve itself.

Ballance and Duel carried out exhaustive researches on monkeys and showed that grafting

the facial nerve in the fallopian canal is usually more successful than grafting of other peripheral nerves.

Unfortunately, too many facial palsies are seen following mastoid operations in which not only may the nerve be severed but there may be actual destruction of a portion of the nerve so that direct suture is impossible. In these cases the insertion of a graft from a superficial cutaneous nerve has brought about results just as satisfactory as the nerve anastomoses and without the accompanying movements of the shoulder or tongue.

Permanent injury to the fifth cranial nerve is seldom seen in facial trauma. When it does occur the only result is anesthesia of the area of distribution of the affected branch, or perhaps paralysis of the muscles of mastication on one side. This leads to little or no difficulty and surgical repair is not indicated.

It is thus seen that practically the only neurological complications of injuries about the face are a transient ophthalmoplegia, anesthesia of the face, or facial paralysis. In rare cases in which permanent nerve injury occurs the only one demanding treatment is paralysis of the seventh or facial nerve.

The operation of choice for facial paralysis is direct suture of the divided nerve. If this is impossible, nerve grafting should be resorted to, and as a last resort, if the previous operations cannot be accomplished, or if the results are not satisfactory, anastomosis of a neighboring motor nerve to the distal portion of the paralyzed nerve may be done.

I have had the opportunity to take part in the treatment of facial paralysis following mastoidectomy. An otolaryngological confrere, Dr. William H. Jenkins, of Washington, D. C., and I have operated on several of these patients with very satisfactory results. The injuries, of course all occurred to that portion of the nerve in the fallopian canal. They ranged from incomplete division to total division, or to dehiscence of as much as 30 millimeters.

Direct suture was possible in 1 case. Grafting of a portion of the external cutaneous nerve of the thigh, or of the sural nerve from the calf of the

leg had to be done in 3 cases. They all show beginning return of motion in about 5 months. Excellent results occurred in an average of 3 months. In no case was there failure to obtain voluntary motion and complete restoration of the facial symmetry.

BODY SECTION ROENTGENOGRAPHY AS A DIAGNOSTIC AID TO THE OTOLARYNGOLOGIST

SHERWOOD MOORE, M.D. and ALFRED J. CONE, M.D. F.A.C.S., St. Louis, Missouri

MANY surgeons are familiar with some form of body section roentgenography and what it can accomplish, but, for the benefit of those who have had no contact with this method, a brief review of its history and the principles involved is in order.

The ordinary roentgenogram is really a composite of all the structures lying in the path of the x-ray beam, because all structures capable of absorbing the ray cast their shadows. Unwanted shadows cannot be separated in ordinary roentgenography except by varying the tube-object relationship and by making stereoscopic films. These leave much to be desired. The superfluous images greatly limit the usefulness of roentgenography and their elimination has always been one of the chief problems of the radiologist.

Bocage (3) of Paris was the first worker to attack this problem successfully. He found that unwanted shadows could be dispensed to a remarkable degree by imparting co-ordinated, synchronized movement of x-ray tube and film about a fixed point during the exposure. All objects in the plane about which movement took place would be so to speak, "in focus" and clearly defined on the roentgenogram and those outside

of the plane, out of focus and blurred on the roentgenogram. Bocage devised an apparatus for carrying out this principle and applied for patent in 1921. He did not construct his machine which he called the *bootème* until 1938 (4) as in the meantime several other investigators working independently had discovered this principle and devised other types of apparatus. Between 1921 and 1938 there appeared the *stratigraph* Valleboma, the *planigraph* of Ziedses des Plantes, the *tomograph* of Grossmann and Chouval, the *laminagraph* of Kleffer and several modifications of these. Each worker coined a term for the type of roentgenography done with his apparatus, and as a result, the literature contains discussions of "stratigraphy," "planigraphy," "tomography" and "laminagraphy" all more or less synonymous and used indiscriminately. To avoid the confusion which naturally results from such multiplicity of names, we have strongly urged the "stratigraph," "planigraph," etc., be restricted to work done with the apparatus from which each word is derived, and that a generic term be used to cover work done with all these types of apparatus, and have used "body section roentgenography" consistently for this purpose. Among the words suggested by others is Bocage's "radiotomie," which if Anglicized and popularized would be most satisfactory because of its etymological correctness. A more elaborate discussion of the chronological development of body section

From the Edward Mallinckrodt Institute of Radiology and the Department of Otolaryngology, Washington University School of Medicine.

Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 2-5, 1940.

roentgenography will be found in the publications of Andrews

In all body section roentgenography, regardless of the method and apparatus employed, there is the same objective in view. This is to disperse overlying and underlying shadows and leave a selected layer in the body relatively unobscured. Another objective is to visualize as thin a layer as possible because minimal contrast in density in such a layer can be brought out. This is called the "depth of focus" of the apparatus. As a general rule, the more compound the movement of tube and film during exposure, the more efficient the dispersion of unwanted shadows. These two points comprise the fundamental value of body section roentgenography in normal anatomical structures. When pathological states produce abnormal increase of density or the converse, or induce unwanted shadows, body section roentgenography is of the utmost value.

The clinical work which will be presented was done with the laminagraph, which was invented by Mr. Jean Kieffer, of Norwich, Connecticut (Fig 1). This apparatus differs from all other types and combines all the mechanically possible co-ordinate movements of tube and film, as far as known, and these can be varied as desired. The spiral movement has proved the most satisfactory, and in routine clinical work we have used it almost exclusively. With this movement the laminagraph

Fig 2 Position of patient for laminagraphic examination of the paranasal sinuses. Films made at 4, 5, and 6 centimeters from the table top usually suffice.

has demonstrated superiority in the symmetry of its dispersion of unwanted shadows, or blurring. Like the tomograph and its simpler modifications, our apparatus can be used only with the patient in the recumbent position, whereas the com-

Right, laminogram: 1.4 centimeters.

mercial planigraph, the biotome and the stratigraph utilize the erect position.

In considering the clinical applications of this method, one must constantly keep in mind its

Fig. 4b

primary objective: the dispersion of overlying and underlying shadows. It follows that in those regions where there is a maximum of these shadows the method will be of the greatest value.

Fig. 6b

Unwanted shadows produced by a pathological process have, in our experience, been most frequent in the respiratory tract. In certain of its portions there are a number of normal structures, the shadows of which it is desirable to eliminate, for example the bones overlying the paranasal sinuses, the ribs and sternum in the chest, and the spine in the region of the larynx. It is in this field that body section roentgenography has its forte and its usefulness has been repeatedly demonstrated by many workers.

In the examination of the chest, of which we have made 40 laminagrams, we have found cavities and consolidation in the lungs which were not apparent either roentgenoscopically or in conventional films. The method has been of little value in early croup disease in the lungs. However excavation has been shown where there was minimal change. It is undoubtedly true that the absence of grosser changes, such as cavity and consolidation, can be established with the same degree of accuracy as their presence.

The location, size and physical characteristics of pulmonary cavities can be accurately determined. Therefore, the surgeon, knowing in advance the exact location and nature of the lesion, can plan his approach with assurance.

The laminagraph can clearly reveal the tracheo-bronchial tree and has revealed bronchial branches as small as 3 to 4 millimeters in diameter. Dis-

location impingement or distortion, and termination through obstruction have been clearly shown. In cases in which carcinomatous infiltration has been diffuse absence of bronchial branches has been shown, and dislocation of branches in the adjacent, healthy lung has also been revealed. Of course, this applies only to those early cases in which suppuration and abscess formation have not occurred.

In the examination of the paranasal sinuses the problem of superimposed structures has always been troublesome, and 3 years ago we predicted that "laminagrams should add materially in such conditions as petrositis of the temporal bone conditions involving the temporomandibular joint and deep-seated paranasal sinuses, to mention only a few anatomical regions. At present, so accurate is the laminographic diagnosis of paranasal sinus disease that requests for these films by the otolaryngological surgeons are sent in almost daily (Fig 2).

The second basic principle of body section roentgenography, namely the thinness of the layer roentgenographed, is important in the examination of the paranasal sinuses because it has bearing on the minimal contrast in density. In the examination of the ethmoid cells laminagrams reveal the size, position, extensions, and other anomalies, and the pathological states far beyond anything possible with standard x-ray procedures,

Fig 6c

Fig 6d

Fig 6e

Fig 6f

(Legend on opposite page)

however extensively they may be carried out. This is also true of the sphenoid group both in the anteroposterior and lateral projections. The conventional films of the maxillary sinuses generally

suffice, but there is the occasional case in which a pathological condition is revealed with lamina-grams when it was entirely unsuspected even when contrast media were employed

Fig. 6a

Fig. 6b

Unwanted shadows produced by pathological process have, in our experience been most frequent in the respiratory tract. In certain of its portions there are a number of normal structures, the shadows of which it is desirable to eliminate, for example the bones overlying the paranasal sinuses, the ribs and sternum in the chest, and the spine in the region of the larynx. It is in this field that body section roentgenography has its forte and its usefulness has been repeatedly demonstrated by many workers.

In the examination of the chest, of which we have made 410 laminagrams, we have found cavities and consolidation in the lungs which were not apparent either roentgenoscopically or in conventional films. The method has been of little value in early acute disease in the lungs. However excavation has been shown where there was minimal change. It is undoubtedly true that the absence of grosser changes, such as cavity and consolidation, can be established with the same degree of accuracy as their presence.

The location, size, and physical characteristics of pulmonary cavities can be accurately determined. Therefore, the surgeon, knowing in advance the exact location and nature of the lesion, can plan his approach with assurance.

The laminagraph can clearly reveal the tracheo-bronchial tree and has revealed bronchial branches as small as 3 to 4 millimeters in diameter. Dis-

location, impingement or distortion and termination through obstruction have been clearly shown. In cases in which carcinomatous infiltration has been shown and dislocation of branches in the adjacent, healthy lung has also been revealed. Of course this applies only to those early cases in which suppuration and abscess formation have not occurred.

In the examination of the paranasal sinuses the problem of superimposed structures has always been troublesome, and 3 years ago we predicted that "laminagrams should aid materially in such conditions as petrositis of the temporal bone conditions involving the temporomandibular joint and deep-seated paranasal sinuses, to mention only a few anatomical regions. At present, so accurate is the laminographic diagnosis of paranasal sinus disease that requests for these films by the otolaryngological surgeons are sent in almost daily (Fig. 3).

The second basic principle of body section roentgenography namely the thinness of the layer roentgenographed, is important in the examination of the paranasal sinuses because it has bearing on the minimal contrast in density. In the examination of the ethmoid cells laminagrams reveal the size, position, extensions, and other anomalies, and the pathological states far beyond anything possible with standard x ray procedures,

this method when it is impossible to do so with conventional films because this joint is heavily overlaid by the zygomatic process and other bony structures. Deformities, erosion, and fractures of the condyle and glenoid fossa have many times been revealed, and the laminagraph has proved of great value in the diagnosis and treatment of the "temporomandibular syndrome." This has been reported by Bleiker and by Pippin and associates.

The larynx can be investigated to great advantage by this method as has been demonstrated by Canuyt and Gunsett, in France, Leborgne, of Montevideo, and Howes and Caulk, in this country (Fig. 3). Mobility of the vocal cords can be investigated in different phases of phonation, and deviation of the air columns in the larynx, encroachment on the air passages by new-growth and edema, and increase in its size through ulcerating processes can be clearly shown. This is of particular value in the subglottic region, inaccessible to the laryngoscope. The exact clinical value in the diagnosis of subglottic regions has not yet been established. Leborgne considers this method of great value but properly states that it should be supplemented by direct laryngoscopy and also the lateral standard view of the larynx. We cannot agree to the importance of the latter. In our experience certainly the lateral laminagrams of the larynx have been valueless probably because that structure is too great a distance from the film for this type of examination.

By varying our factors during $3\frac{1}{2}$ years of experience we have worked out a technique for the laminagraphic examination of the paranasal sinuses which has become approximately standard in our clinic. This has been described elsewhere. In general it may be said that standard roentgenography should always precede the laminagraphic examination so that the films may be used as a guide. When the laminagrams are made, the patient is placed in the prone position with the plane of the face parallel to the top of the table. In the routine method, films are made at 4, 5, and 6 centimeters from the plane of the face. This covers the anterior and posterior ethmoid cells and the sphenoids. These planes were established by experimental work with cadaver heads and are, for all practical purposes, accurate. As has been previously stated, the standard film usually suffices in the examination of the maxillary antra, but occasionally laminagrams are needed, not only for the maxillary antra, but also for the frontal sinuses. In that event additional laminagrams are made. For the frontal sinuses these are 0.5 and 1 centimeter, and, if the frontal sinuses have a great anteroposterior dimension, $1\frac{1}{2}$ to 2 centi-

meters in addition. To cover the maxillary antra laminagrams at 2 and 3 centimeters in addition to the routine 4 centimeter film are sufficient.

Sluder stated, "The x-ray, in my experience, has failed to help in the diagnosis of hyperplastic post-ethmoidal and sphenoidal disease. It is of paramount value in determining cell anomalies, showing probes in positions which determine these."

Cone, Moore, and Dean reported on the relationship of paranasal sinus disease to ocular disorders as studied by laminagraphy. Changes in density of the posterior sinuses and variations in development were demonstrated. Pathological studies of tissue removed and the clinical improvement after treatment suggest that sinus disease is an important cause of ocular involvement.

S. Salinger has informed us regarding a patient with optic neuritis in whom disease of the posterior sinuses was discovered by laminagraphy. Conventional roentgenography was inconclusive. Recovery followed surgical drainage of the sinuses. Weve and Ziedses des Plantes reported a case of optic atrophy and paresis of the extra-ocular muscles due to an isolated lesion in the ethmoid bone which was not seen in the routine roentgen films but which showed up beautifully in the planigraphic studies at a depth of 5 centimeters.

Sluder, in 1927, stated,

"The frequency of headache without recognizable systemic or organic neurological basis is well known. The mystery of the etiology of many eye lesions is well known. From a very extensive experience with such cases I am led to the belief that their explanation is to be found in the hyperplastic lesion of the post ethmoidal-sphenoidal district, to a degree of frequency that, could it be put into percentages, would astonish us all, however familiar we may be with such cases. At the same time it must be clearly understood that I do not at all believe that lesion to be the explanation of all such cases."

Today the relationship of sinus disease to ocular disturbance remains controversial. The frequency of optic-nerve involvement in patients with multiple sclerosis is well known. It has been suggested that not only the optic-nerve involvement but also the lesions of multiple sclerosis may be caused by invasion of the nervous system by way of the sinuses. Stark stated, "one (multiple sclerosis) being an advanced stage of the other (retro-bulbar neuritis)."

The improved methods of study of virus diseases and their possible extension by way of the respiratory mucous membrane has been reviewed in the Harvard Symposium (17). It is possible that numerous controversial questions may be answered when more exacting studies are made.

The value of laminagraphy is best demonstrated by the unquestionable information which its use

Fig. 7. Case 4, J. W. These two laminograms illustrate marked differences in densities in the ethmoid and maxillary sinuses. The film above is pre-operative, that below postoperative. Both were made at 5 centimeter depth. The patient was a child with an orbital involvement secondary to sinus disease.

Fig. 8. Case 5, L. B. This laminogram at 4 centimeters above the bilateral involvement of the ethmoid sinuses in a patient suffering from bilateral retrobulbar neuritis. The history in this case was previously reported and is included here only because it is our firm belief that laminography will prove to be of the greatest value in patients with posterior sinus disease and serious eye disorders in whom all other methods of examination may be unsatisfactory.

So far we have made no practical application of this method for studying the pneumatic structure of the temporal bone. However the auditory canals can be revealed throughout their extent in those rare cases of non-development of the auricle. This is the most accurate way of establishing enlargement of the internal auditory meatus in suspected eighth nerve tumors. We have had operative confirmation of laminographic findings in 3 cases. Any alteration of the auditory canal, either enlargement through soft tissue growth or decrease in size through bony growth, is discoverable with this method. The presence and the size or the absence of the groove for the lateral sinus can be shown in adults. However it is improbable that this would be possible in younger patients because of slight development of the groove, and unfortunately it is in such cases that this knowledge would be of the most value. There is evidence to suggest that a thrombosis of the lateral sinus can be visualized with laminograms.

The condition of the articulation of the mandible with the temporal bone can be established by

this method when it is impossible to do so with conventional films because this joint is heavily overlaid by the zygomatic process and other bony structures. Deformities, erosion, and fractures of the condyle and glenoid fossa have many times been revealed, and the laminagraph has proved of great value in the diagnosis and treatment of the "temporomandibular syndrome." This has been reported by Bleiker and by Pippin and associates.

The larynx can be investigated to great advantage by this method as has been demonstrated by Canuyt and Gunsett, in France, Leborgne, of Montevideo, and Howes and Caulk, in this country (Fig 3). Mobility of the vocal cords can be investigated in different phases of phonation, and deviation of the air columns in the larynx, encroachment on the air passages by new-growth and edema, and increase in its size through ulcerating processes can be clearly shown. This is of particular value in the subglottic region, inaccessible to the laryngoscope. The exact clinical value in the diagnosis of subglottic regions has not yet been established. Leborgne considers this method of great value but properly states that it should be supplemented by direct laryngoscopy and also the lateral standard view of the larynx. We cannot agree to the importance of the latter. In our experience certainly the lateral laminagrams of the larynx have been valueless probably because that structure is too great a distance from the film for this type of examination.

By varying our factors during $3\frac{1}{2}$ years of experience we have worked out a technique for the laminagraphic examination of the paranasal sinuses which has become approximately standard in our clinic. This has been described elsewhere. In general it may be said that standard roentgenography should always precede the laminagraphic examination so that the films may be used as a guide. When the laminagrams are made, the patient is placed in the prone position with the plane of the face parallel to the top of the table. In the routine method, films are made at 4, 5, and 6 centimeters from the plane of the face. This covers the anterior and posterior ethmoid cells and the sphenoids. These planes were established by experimental work with cadaver heads and are, for all practical purposes, accurate. As has been previously stated, the standard film usually suffices in the examination of the maxillary antra, but occasionally laminagrams are needed, not only for the maxillary antra, but also for the frontal sinuses. In that event additional laminagrams are made. For the frontal sinuses these are 0.5 and 1 centimeter, and, if the frontal sinuses have a great anteroposterior dimension, $1\frac{1}{2}$ to 2 centi-

meters in addition. To cover the maxillary antra laminagrams at 2 and 3 centimeters in addition to the routine 4 centimeter film are sufficient.

Sluder stated, "The x-ray, in my experience, has failed to help in the diagnosis of hyperplastic post-ethmoidal and sphenoidal disease. It is of paramount value in determining cell anomalies, showing probes in positions which determine these."

Cone, Moore, and Dean reported on the relationship of paranasal sinus disease to ocular disorders as studied by laminagraphy. Changes in density of the posterior sinuses and variations in development were demonstrated. Pathological studies of tissue removed and the clinical improvement after treatment suggest that sinus disease is an important cause of ocular involvement.

S. Salinger has informed us regarding a patient with optic neuritis in whom disease of the posterior sinuses was discovered by laminagraphy. Conventional roentgenography was inconclusive. Recovery followed surgical drainage of the sinuses. Weve and Ziedses des Plantes reported a case of optic atrophy and paresis of the extra-ocular muscles due to an isolated lesion in the ethmoid bone which was not seen in the routine roentgen films but which showed up beautifully in the planigraphic studies at a depth of 5 centimeters.

Sluder, in 1927, stated,

"The frequency of headache without recognizable systemic or organic neurological basis is well known. The mystery of the etiology of many eye lesions is well known. From a very extensive experience with such cases I am led to the belief that their explanation is to be found in the hyperplastic lesion of the post-ethmoidal-sphenoidal district, to a degree of frequency that, could it be put into percentages, would astonish us all, however familiar we may be with such cases. At the same time it must be clearly understood that I do not at all believe that lesion to be the explanation of all such cases."

Today the relationship of sinus disease to ocular disturbance remains controversial. The frequency of optic-nerve involvement in patients with multiple sclerosis is well known. It has been suggested that not only the optic-nerve involvement but also the lesions of multiple sclerosis may be caused by invasion of the nervous system by way of the sinuses. Stark stated, "one (multiple sclerosis) being an advanced stage of the other (retro-bulbar neuritis)."

The improved methods of study of virus diseases and their possible extension by way of the respiratory mucous membrane has been reviewed in the Harvard Symposium (17). It is possible that numerous controversial questions may be answered when more exacting studies are made.

The value of laminagraphy is best demonstrated by the unquestionable information which its use

permits in showing variations in cell development. Interpretation of varying densities of individual cells may remain controversial. The possibilities are shown in the cases which illustrate this text.

In evaluating body section roentgenography it is well to remember that this method must be judged as an adjunct to conventional roentgenography and not as a substitute for it. As such it is an invaluable aid to the otolaryngologist, for laminagrams reveal changes in the sinuses undiscernable by other methods and should be used *if a sincere effort in establishing the diagnosis is to be made.*

TRENDS IN CATARACT SURGERY

JOHN HUGHES DUNNINGTON, B A , M D , F A C S , New York, New York

THE vast amount of literature appearing within the past decade is definite evidence that interest in cataract surgery is not waning. It is also proof that steady progress is being made, for while not every article is a real contribution it does show thought and out of so much thought must come some good. For example the presentation of so many variations in cataract sutures, although confusing, has made us realize the desirability of accurate wound closure. Similarly the oft-repeated debate of extracapsular versus intracapsular extraction has led to the realization that each has its place.

Preliminary examination During this decade our attention has been directed repeatedly to the necessity for careful pre-operative physical study of every patient, although little that is new has appeared. While reporting on postoperative complications Berens and Bogart have pointed out the prophylactic value of such an examination. The pre-operative administration of vitamin C has been advocated by Urbanek and Albrecht on the theory that old patients with cataracts frequently have vitamin deficiencies. More care is taken to control the diabetic and arteriosclerotic patient before operation but in general no great advances have been made.

A necessary part of the complete ocular examination should include a measurement of the intra-ocular tension. This point, which was emphasized for many years by the late John M. Wheeler as a safeguard against the coexistence of glaucoma and cataract, has recently been adopted as a routine measure.

The value of conjunctival smears and cultures as a pre-operative prophylactic measure is still debated. There are some, e.g., Gailey, Herrenschwand, and others, who are of the opinion that they are useless, while others, Elschning, Kapuscinski, and others, will not operate in the presence of a positive smear—gram positive diplococci—without culturing the organism on bouillon and blood agar plates to determine its pathogenicity. Pre-operative treatment of the conjunctiva is also not standardized. Elschning and Goar use oxy-cyanide of mercury 1:5000 and Wright (55) 10 per cent argyrol for one week before operation while others

use 0.5—1 per cent silver nitrate or argyrol 25 per cent one hour before operation and still others use nothing but thorough lavage on the operating table. The advisability of pre-operative sedatives seems generally accepted. Those most favored at the present time are nembutal and sodium amytol.

Anesthesia In addition to the usual instillation of a local anesthetic some form of akinesia is widely used. In 1914 Van Lint described his method of producing a temporary paralysis of the branches of the facial nerve by infiltration anesthesia along the outer orbital margin. After several modifications this was followed by Wright's (56) suggestion in 1923 that the nerve be blocked at its point of emergence from the stylomastoid foramen. O'Brien, in 1929, described his technique for blocking the facial nerve at a point just external to the condyle of the inferior maxilla. The necessity for some form of akinesia is so universally recognized today that it is difficult for us to realize the newness of this safeguard.

The retrobulbar injection is not new, for one finds that Hermann Knapp, in 1884, used it successfully in a case requiring an enucleation. However, its widespread use in cataract surgery is of comparatively recent date. Enthusiastic approval of retrobulbar anesthesia is shared by many but few go as far as McCool and Dickey in believing that "if we were obliged to discard all the measures which we use to safeguard the eye, save one, we would unhesitatingly retain retrobulbar injection." The fear of an orbital hemorrhage has caused some operators to use instead an injection into Tenon's capsule, for example, Stallard. Still others, Hartshorne, for example, point out that satisfactory anesthesia can be accomplished by local instillations and subconjunctival injections. Although orbital hemorrhages do follow retrobulbar injections it is rare, as was strikingly shown by Atkinson. He collected data on 8,000 retrobulbar injections and found only 8 orbital hemorrhages, 5 of which were admittedly due to faulty technique. He correctly urges the use of a 3/5 centimeter needle as a safeguard against vessel injury at the apex of the orbit. Arruga believes that the use of a sharp needle is contra-indicated while Elschning stresses the importance of quick energetic compression immediately after the injection. Gailey, Kubik, and others think that a slow injection of novocain ahead of the tip of the

From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University.
Presented before the Clinical Congress of the American College of Surgeons, Chicago, October 21-25, 1940.

needle reduces the frequency of an orbital hemorrhage. The reduction in intra-ocular tension which follows the injection is the strongest argument for its use in intracapsular extraction and is a definite hindrance to its use in extracapsular extraction. Those operators using the extracapsular extraction exclusively rarely employ it, while those using both methods use it only when the intracapsular extraction is contemplated.

Davis (10) Laval, Spaeth (48) and others have reported the successful use of avertin anesthesia in cataract extraction in unco-operative patients. Graves has advocated paraldehyde anesthesia per rectum supplemented by omnopon. The newer intravenous anesthetics have also been used—Frankschuetz, Gil, and Stallard—but the vast majority of surgeons still use a local anesthetic.

Retraction suture. The forceps fixation of the superior rectus as described by Angelucci has been supplanted by the use of a retraction suture under this muscle. This method of controlling the movement of the eyeball has gained in popularity until today it is looked upon by many as one of the necessary safeguards in cataract extraction. Most operators pass a suture through the conjunctiva and the stump of the superior rectus. Graves, however, believes that the conjunctiva should be dissected up and the suture introduced into the tendon alone. Bartels and Wright (56) think that the use of the suture predisposes to prolapse of the vitreous because if too much traction is made upon it in an endeavor to direct the gaze downward a dangerous bulging of the wound occurs. Beach and McAdams, Lowenstein, Saint Martin, Vogt, and others urge akinesia of the superior rectus instead of the suture as the safest method to prevent an upward rolling of the eye. It can be said that some form of control over the upward movement of the globe is very desirable in unco-operative cases. It is true the suture has certain disadvantages but akinesia producing a complete inability to rotate the eye upward predisposes to wound gaping and vitreous loss. It seems logical therefore to introduce the suture and employ it whenever needed. It should be gently held and if the patient does not co-operate satisfactorily not unduly drawn on particularly after delivery of the lens as this may cause vitreous prolapse (Buxton). The use of akinesia has diminished the frequency of the need of canthotomy but it is advocated in prominent eyes or whenever the lids exert even the slightest pressure upon the globe in the region of the external canthus.

Incision. The corneal incision is used by a few operators who believe that a conjunctival flap is too bloody (Appelmann, Jackson) but the vast

majority of surgeons prefer some form of conjunctival flap. Various techniques have been described some prepare the flap before starting the incision while others make it with the cataract knife and leave a conjunctival bridge. Wright (56) O'Connor McReynolds, and others advocate the conjunctival bridge in complicated cataracts. It was suggested as a safeguard prior to the use of sutures and while still employed is less widely used now that the value of accurate wound closure is so generally accepted.

Most surgeons still prefer the Graefe cataract knife for making the incision although a few advocate a keratome incision enlarged with scissors. This method has never gained in popularity. In this connection one notices that many cataract sections are made small to insure proper location and to avoid injury to the iris and then subsequently enlarged with scissors—a justifiable procedure whenever one is operating in the presence of a shallow anterior chamber but not with one of normal depth. A section made with scissors is rarely as smooth as one made with a knife. Scattered throughout the literature one finds the recommendation that in the event of the iris coming in front of the knife during the incision the operator should proceed with the incision, even cutting the iris if necessary. Under these circumstances the operator in his endeavor to avoid the iris makes an incision well anterior in the cornea or if the iris is cut has but little control over the shape, size and position of the coloboma. This teaching was strenuously opposed by the late John M. Wheeler, who believed that the knife should be withdrawn immediately and the section completed with the scissors.

Sutures. As long ago as 1869 Williams advocated suturing the cataract incision, pointing out that by securing a more immediate union, we not only avoid ulceration of the border of the flap and prolapse of the iris with its attendant evils, but the prompt restoration of the fullness of the globe and of the normal relation of its several parts lessens the chances of irritation from pressure of any cortical fragments or remnants of the capsule upon the delicate contiguous structures and the occurrence of iridocyclitis. In spite of this clear cut statement, the truth of which is generally conceded today we find that suturing of the cataract incision has received considerable attention only within the past 30 years. During the past 30 years many variations in technique have appeared and much has been written enlarging upon Williams' dictum. All this has been to good purpose, for it has made the cataract surgeon so sure that today he does not ask if a

suture is necessary, but he does ask which one is best. In 1937 Ellett presented an excellent review of the subject with a discussion of the various types of sutures employed. It is well to review some of the facts set forth by this author, as they show the trend in "sutures for cataract extraction."

The conjunctival suture as initiated by Williams is still widely used. Its chief virtue lies in the ease with which it can be introduced, after the section is completed. Many operators, for instance, Spaeth (48), prefer it for this reason as they want no distracting influence, such as the presence of a corneoscleral suture while making the incision. Since a proper section is so necessary it certainly behooves us to see that the suture does not interfere. If a conjunctival suture is used the flap should be narrow because the elasticity of this membrane is so great that a large flap has practically no splinting effect upon the corneoscleral wound. The experimental work of Hilding is noteworthy, for this worker, using enucleated oxen eyes, made a series of measurements of the intra-ocular pressure necessary to cause prolapse of the iris through limbic incisions under various conditions. From these experiments he concluded that "conjunctival flaps and pockets are essentially ineffective in re-enforcing limbic incisions so as to prevent gaping of the wound and herniation of the iris when healing effects are eliminated." The conjunctival protection of the wound hastens healing but since most iris prolapses occur within the first three postoperative days it is doubtful that the presence of "healing effects" changes the validity of this statement. Leech and Sugar, in their analysis of 450 cataract cases, found that the postoperative complications of (1) prolapse of iris or vitreous or both, (2) delayed closure of the anterior chamber, (3) hyphemia, were much less frequent when sutures were used. The conjunctival suture was found of definite value and the corneoscleral suture of even greater value. Gradual acceptance of the virtues of suturing the wound has led to innumerable variations in technique.

The corneoscleral suture Since Kalt, in 1894, described the first corneoscleral suture it seems as if almost every ophthalmologist has attempted to devise some modification of it, until today hardly any two surgeons employ the same technique. Kalt's method has many advocates, among them being Arnold Knapp and Ellett in this country, whose vast experiences certainly justify our giving serious consideration to this form of wound closure. Kalt describes the method of insertion as follows: "The suture consists of a vertical corneal

portion and a transverse episcleral portion. The whole forms a T with a gap between the junction of the horizontal portion with the vertical portion. The length of each of the portions does not exceed 1 millimeter. The vertical intracorneal branch follows the vertical corneal meridian and stops exactly at the junction of the transparent portion with the sclera. The horizontal portion traverses the opaque part of the limbus as near the cornea as possible. An interval of 0.5 millimeter corresponding to the limbus is ample to permit the passage of the knife." Liegard modified this suture by placing both bites horizontally. This type of suture is strongly endorsed by Stallard (49), Leech and Sugar, and others. McLean recently published a description of an effective corneoscleral suture in which after dissecting down a small conjunctival flap a small slot is made at the base of the flap about half way through toward the anterior chamber. A fine black silk suture is then run through the base of the conjunctiva and then through both the scleral and corneal lips emerging in clear cornea just below the base of the conjunctival flap. The increased efficiency of corneoscleral sutures over conjunctival sutures in reducing the number of postoperative complications has been stressed by many (Ellett, Stallard, Lindner) and statistically shown by Leech and Sugar. Among their conclusions were (1) the number of postoperative prolapses is reduced and when prolapse does occur it is smaller; (2) the occurrence of hyphemia is reduced, (3) anterior chambers are reformed earlier, (4) prolapse of the vitreous is eliminated. They also pointed out the advantages of greater postoperative freedom to the aged who with this safeguard can be allowed up within 24 to 48 hours after operation.

Today the indecision rests not upon the value of the corneoscleral suture but upon the best time and way to introduce it. One finds many experienced operators who insert their sutures after the section is completed and others who introduce them before the eyeball is opened. The increased sharpness and delicacy of the atraumatic corneal needles greatly facilitate their introduction after the section is made. However, judging from my experience and observation, sutures introduced at this stage are much less accurately placed and sometimes the operator has to be content with a conjunctival closure, or else run too great a risk in attempting to pick up the sclera. The placing of the suture while the eyeball is still intact is safer although its presence tends to interfere with the smoothness of the section. Nothing must be allowed to interfere with the section, but very little is lost if the suture is severed by the knife.

It can be reinserted upon completion of the section just as easily if not more easily than the original introduction.

Iridectomy. The popularity of the preliminary iridectomy has gradually receded, except in England, and today it is used as a routine measure by comparatively few operators. Its usefulness in dislocated lenses was stressed by Wheeler and as he so aptly pointed out these iridectomies should be broad. Many operators, such as Davis (11), O'Connor and Gracie use it only in complicated cases. It seems logical to state that in any case with vitreous in the anterior chamber or when vitreous loss is almost certain to occur its use is definitely indicated.

Although a complete iridectomy at the time of extraction is favored by many competent and experienced operators, notably Knapp, Davis (11), Appleman, and others, the trend is definitely toward extraction with a round pupil. Ellett, Peter Verhoeff, Bracken, and many others have commented upon the advantages of retaining the iris sphincter. Its presence is said to assist in preventing prolapse of the vitreous in the intracapsular extraction and to lessen the chances for capsular and cortical incarceration in extracapsular extraction. It is generally agreed that an iridotomy or peripheral iridectomy lessens the chance of iris prolapse. Hilding's experimental work, previously quoted, showed that an iridotomy opening added to the sclerocorneal suture made it almost impossible to produce prolapse when the opening acted well. This would seem to indicate that the opening to be of value must be large enough to permit free passage of fluid from the posterior chamber to the anterior chamber. The increased frequency of iris prolapse when a round pupil is attempted is not universally admitted but the majority of operators definitely feel that such is the case. A careful pre-operative study of the iris and lens may prove helpful in reducing the occurrence of this complication. A loss of resiliency in the iris from sclerosis, atrophy, adhesions, or any cause tends to increase the chances of iris prolapse. These cases in my opinion should have a complete iridectomy. As Wright (56) has pointed out there is increased difficulty in delivering the lens in its capsule or a large nucleus in extracapsular extraction in the presence of a rigid pupil. In this group he favors an iridotomy including the sphincter in preference to a complete iridectomy. Just 10 years ago Lancaster in an address before this society stressed the advantages of a basal iridectomy over a complete iridectomy. He believes that a basal iridectomy is even better as a preventive of prolapse than a

complete iridectomy pointing out that it prevents capsule complications and at the same time avoids most of the iris complications. Within the past decade the truth of these statements has been appreciated more and more until today the complete iridectomy is no longer a routine procedure but is used whenever the operator encounters definite contra-indications to a peripheral one. Even though corneoscleral suturing and consideration of the contra-indications to peripheral iridectomy have materially reduced the number of iris prolapses it is still one of the more frequent complications and its management remains unsettled. Cautioning of the prolapse with trichloroacetic acid is advocated by many—Bothman, Gailev, Magitot, Dubois-Poehen, and Gifford—but others condemn it and suggest excision at the earliest possible moment as the only satisfactory method for curing this condition.

Selection of operation. Probably the most striking change that has occurred in cataract surgery within the past 10 years has been the increasing number of advocates of the intracapsular extraction. The extracapsular method is defended especially by Jackson, Moehle, Wright (56) and others, but the number of experienced operators who routinely use the extracapsular extraction is diminishing. Davis (11) for example after using exclusively the extracapsular method for 19 years is enthusiastic over the smooth postoperative course of his intracapsular cases. Gracie believes "In the hand of the experienced operator the Elchnaf method of intracapsular extraction is just as safe if not more so than the older capsulotomy method. On the other hand Fiechel after an analysis of a series of cases done by both methods concludes "while the results in the successful intracapsular operation are practically as good as those in the well performed extracapsular operation, there were more bad results even in a selected series of cases of intracapsular operations than in an unselected series of extracapsular operations."

Thus it would seem that the important consideration in cataract extraction is the selection of the proper type of operation. It is not within the realm of this paper to discuss the indications for the intracapsular operation which have been so concisely given by Arnold Knapp who believes, "There is more or less general unanimity in the selection of cataracts that are suitable for this operation. The recent improved methods of anesthesia and other aids have greatly reduced the list of contra-indications. Unfortunately however the tendency has become more and more prevalent to attempt an intracapsular extraction

on almost every case. One often hears that nothing is lost if the capsule ruptures and the lens has to be extracted by the extracapsular method—a teaching which in my opinion should be condemned. We have all had the capsule tear after dislocation has taken place and been forced to deliver as best we can a sticky, partially opaque lens. Under these conditions the removal of the cortical matter by irrigation or by mechanical means is not without added risk and the usual result is that a large portion of it remains. It often lies in the upper part of the anterior chamber more or less in contact with the wound. Secondary glaucoma is not an infrequent sequela. The intumescent cataract which is generally recognized as unsuitable for intracapsular extraction is the most frequent cause of this complication. Similarly failure to consider other contraindications may produce disastrous results.

Within the past 10 years there has been no appreciable change in the technique of the extracapsular extraction, but many articles have been written upon modifications of the intracapsular operation. Without entering into a discussion on the merits of these various methods it is sufficient to say that the technique most frequently employed is the so called forceps and pressure method. No uniformity of opinion exists on the best way to apply the forceps, but the majority believe that they should be used only to control the delivery of the lens which is largely expressed by pressure. Some (Knapp, Peter, Elschning, and others) insist upon tumbling the lens while others (Beach and McAdams and Verhoeff) apply the forceps above in the equatorial region and extract the lens head on. The cresophake, as designed by Barraquer, has its advocates and many modifications of this instrument have appeared but its use has never become widespread. Saint Martin suggests that it is ideally suited for the intracapsular extraction of the intumescent cataract in which the forceps method is so often unsuccessful—a thought worthy of further investigation, for if we could succeed in extracting these lenses without rupturing the capsule much trouble would be averted.

Wright (56) with an enormous experience of over 20,000 cases correctly sums up the situation in the words: "Dogmatism in connection with the various procedures of the operative treatment of cataract is not uncommon, as one may judge who follows up current literature, but the greater one's experience the more inclined one is to adopt an open mind. A man may indulge in dogmatism when he has collected figures in connection with 100 cases of the operative treatment of cataract

but he will be less inclined to do so after his thousandth extraction and completely alter many of his previous views after his five thousandth case." There are few if any of us who will ever perform such a vast number of cataract extractions. Nevertheless the truth of this statement can not be denied. Let us, therefore, realize that there are indications for the extracapsular as well as for the intracapsular extraction and strive constantly toward a perfection of these indications.

THE 1940 CLINICAL CONGRESS

THE COLLEGE AND AMERICAN SURGERY

GEORGE P MULLER, M D, F A C S, Philadelphia, Pennsylvania

A PRESIDENTIAL address in my opinion should give an account of the affairs of the organization, an accounting for stewardship as it were. The American College of Surgeons is fortunate in having a splendid organization with minute and detailed reports available, and hence its president has but little to do. Therefore, it seems to me that this address might serve to welcome the initiates who shortly will become Fellows of the College and also to discuss certain details of the College, its aims, and objectives.

Most of the successful ventures in human endeavor come from organization and we think this is particularly true of medicine. The labor union exists for the purpose of improving the economic status of its members, the medical association or college exists to improve the scientific attainments of its members by organized effort.

The foundation of the American College of Surgeons sprang from an idea. In 1903, the Society of Clinical Surgery was organized for the purpose of demonstrating to a group of surgeons the methods used in different leading clinics. The effort was most successful and naturally as surgeons from different cities watched each other work, they were bound to carry home with them the best of the surgical procedures they had observed. Apparently this gave to Franklin Martin, of Chicago, the idea of organizing a greatly magnified and practical clinic.

In 1910, in Chicago the Clinical Congress of Surgeons of North America was organized, and 1,300 surgeons were in attendance. The organization was rather loose and Martin, with characteristic foresight, saw the possibility of banding these men together in an organization which would stand for the uplift of surgical principles and technique and practice. Hence, he formulated the organization of the American College of Surgeons in 1913, and after a founders' group had been formed, 1,059 initiates were enrolled into fellowship at the first Convocation.

In the Articles of Incorporation it is stated that the object for which the American College of Surgeons is formed is

"to establish and maintain an association of surgeons, not for pecuniary profit but for the benefit of humanity by advancing the science of surgery and the ethical and competent practice of its art, by establishing standards of hospital construction, administration, and equipment, and all else that pertains to them, by engaging in scientific research to determine the cause, nature, and cure of disease, by aiding in better instruction of doctors, by formulating standards of medicine, and methods for the improvement of all adverse conditions surrounding the ill and injured wherever found. To accomplish these benevolent and charitable aims, it shall be within the purposes of this corporation to use those means which from time to time may seem to it wise, including research, publication, education, the establishment and maintenance of libraries, museums, and other agencies or institutions appropriate hereto, and the co-operation of any other such activities, agencies, or institutions already established or which may hereafter be established."

Whoever wrote these sentences wrote a masterpiece because in the twenty-seven years since its organization the College has done every one of these things.

The historic position of the early beginnings of the American College of Surgeons is somewhat different from that of other colleges then in existence. Conforming to the democratic principles of this country, its fellowship was considered inclusive, not exclusive, and it was to be conferred upon surgeons of character, honesty, and ability without particular regard for examination. Certain simple standards were set up, but the supreme test was the recognition of the candidate's fitness by a group of surgeons, Fellows of the College, who knew him best because they worked together in the same community. Therefore, from the beginning the opinion of the State or Provincial Credentials Committee was the dominating influence against the admission of those known to be incompetent or unethical.

It is not so difficult to judge a man's knowledge of the theory and technique of surgery by examination as it is to know that he can apply this knowledge to the individual patient, it is important to know that the surgeon is able to work in a community without friction with his colleagues,

Presidential address of the retiring president presented before the Clinical Congress of the American College of Surgeons, Chicago, October 1-5, 1940

and it is most important to know that he is honest in his relations with the patient. The College makes every effort possible to combat the evil of fee-splitting and while it may not be an issue in all communities and in all hospitals, it has been necessary to establish a uniform regulation to avoid discrimination and to require the medical staff and governing board of every hospital desiring approval to go on record against this practice. Once on record, it is the duty of the hospital management to exercise continuous vigilance to prevent fee-splitting under any guise. The pledge against the division of fees, which is signed by all initiates, was proposed by Dr. Albert Ochsner in Chicago in 1913.

The meeting held each fall is the high point of our College year. The program consists of papers and discussions, of clinics and operations, all illustrative of the progress of the surgery of the day. Those who formulate the program endeavor to give the meeting the benefit of the master minds of surgery. If you would take the time to examine the Clinical Congress programs through the last twenty-seven years, you would read an epitome of the progress of surgery in this country.

In 1910, the College began to organize three or four sectional meetings in different parts of the country each year. They have grown in time so that they almost rival the fall meeting and have been of immense aid in establishing contact with the Fellows of the College.

In a way these meetings are something like other medical meetings, except that they are better and hence it is necessary to look further for the great influence of the College. When we do so we realize that we are part of a great organization exerting a power by the force of our numbers for the good of surgery. If for no other reason, you should be satisfied with your fellowship because, after all, that which concerns the good of surgery as a whole concerns each one of us.

At an early date it was recognized that the hospital and operating room were the laboratories of the surgeon and that many hospital organizations were careless regarding the equipment, the records, and the laboratory facilities. By 1917, the hospital standardization program was well under way and despite the hectic years of the World War our program was developed and a minimum standard for hospitals was adopted in December 1917. Beginning in 1918 the College began a survey of the hospitals of the United States; these surveys have been made every year since until over 3,600 hospitals are now on the survey list and are regularly visited by members of the College staff.

In 1913 at the suggestion of Dr. Thomas Cullen, of Baltimore, a cancer committee was appointed that subsequently formed the nucleus of the American Society for the Control of Cancer. Later the College took over the bone sarcoma registry and in 1922 began assembling data of all cancer cases living five years or more after treatment. The College then established a minimum standard for cancer clinics and organized them in approved general hospitals. Today there are 345 approved cancer clinics.

In the same year under the guidance of Dr. Charles L. Scudder of Boston, exhaustive studies of the present treatment of fractures were conducted and the central fracture committee and regional fracture committees in different states and provinces have become one of the most important details of the College.

In 1926, we organized a board on industrial medicine and traumatic surgery which concerned itself with adequate scientific and ethical care of the ill and injured in industry and this committee, although now fused with the fracture committee has had a beneficial influence and has made many contacts with the large industrial concerns.

From the beginning Canada was included in the organization of the College and in 1920 and subsequent years, Dr. Franklin Martin, William J. Mayo, Thomas Watkins, and others visited the various South and Central American countries, thus binding the surgeons of these countries to the College so that it could be said to be representative of both Americas. As a result of these contacts and because of the standardization program of the American College of Surgeons, Dr. Francis P. Corrigan, now the United States Ambassador to Venezuela and an enthusiastic Fellow of the College, paid a great tribute to the College in his article *El Libro del Mas y tal Moderno*.

The influence of the College was recognized during the first World War when President Wilson appointed Dr. Franklin Martin one of seven civilians to the Advisory Commission of the Council of National Defense. This year Dr. Evans A. Graham, president-elect of the College, has been appointed chairman of the National Research Council Committee on Surgery in connection with the program of military preparedness. The chairman of our Board of Regents, Dr. Irvin Abell, has been appointed chairman of the Committee on Health and Medicine of the Council of National Defense. At the Clinical Congress held in October 1917, the program was indeed a 'war session' and while we are not at war you will notice from the program of the present meeting that we are preparing for defense.

It is interesting to me to note the duplication of thought about the two wars. The high point in the treatment of wounds in 1918 was the Carrel-Dakin irrigation, today it will be sulfanilamide. There will be many improvements in transportation, but I think that the basic surgery will be comparable. There is not a great deal of information in the medical literature of the past year regarding the surgical aspects of the war, yet all surgeons liable to service in the event of war prepare themselves by searching every available source for information regarding the treatment of wounds and other war casualties and the hazards of industry in the conduct of war. As a matter of fact, in a total war, every doctor and every hospital is an integral part of the defense plan.

In his presidential address of last year, Howard Naffziger compared medical progress to a growing stream, the first spring feeding it arising in the far distant past until with the development of modern scientific medicine the stream has become a great river. I do not think it possible to say when and where surgery began because no doubt from the dawn of civilization and even before men attempted to alleviate suffering and injury by some form of material help. At any rate, we do know that much of the practice of surgery began in mystery and magic.

The earliest surgical operation which history records was the trepanning of skulls for the release of demons, presumably the epileptic seizures of the present day. Bloodletting began as a ceremonial procedure. Circumcision was practiced in 4,000 B C according to the picture record and the records in Genesis. In time superstition in medicine disappeared but, despite the enlightening developments of Galen and Celsus, surgery remained in the doldrums until Vesalius early in the sixteenth century taught true anatomy.

Often we hear of an attempt to distinguish between the art of medicine and the science of medicine. Actually, medicine is not a science but gathers its basic knowledge from true science and applies it to the cure of disease, and hence, after Vesalius, anatomical thought ran like a red thread through all of the developments of medical practice. In 1628, eight years after the landing of the Pilgrims, William Harvey announced the theory of the circulation of the blood, thenceforth physiology was inseparably associated with anatomy and surgery became more exact. Harvey taught that speculation alone was valueless, that advances in knowledge would result only from patient experiment, patient measurement, patient application of the method of trial and error, and

that the facts, if they were facts and if there were enough of them, would always speak for themselves. Patiently through the years the science of physiology unfolded its secrets to medicine until today we constantly talk in details of function, and surgery endeavors to restore normal function or to remove an offending organ.

Sometime in the eighteenth century the pupils of the great chemist, Robert Boyle, discovered the different gases in the atmosphere and thus led to the discovery of inhalation anesthesia, the word "anesthesia" having been invented by Oliver Wendell Holmes. In 1584, Fracastorius wrote that contagion is infection passing from one individual to another. Step by step the picture was completed with Holmes, Semmelweis, Pasteur, Koch, and Lister standing out in the foreground. From the time when Lister developed the technique of antiseptics in 1865, surgeons were concerned with methods which combined antiseptics and sterilization by heat and allowed operations to be undertaken safely with ever increasing freedom.

For a long time there was not much progress except the perfection of details for fulfilling the doctrine of antiseptics. In 1910, Ehrlich produced salvarsan and this discovery not only revolutionized the treatment of syphilis but exerted such a stimulus to chemotherapy that today most progress in surgical technique is closely allied with the progress of chemical research.

Surgery benefited from the field of physics when in 1895 Roentgen discovered x-rays. The efficiency of this instrument of diagnosis and treatment has progressed until today, judging from reports which we hear, we may be on the verge of extraordinary developments by the use of the cyclotron. After Roentgen came the Curies and the isolation of radium, and its use particularly in cancer was another step forward.

These few remarks are introduced merely to furnish a backdrop to the stage on which is played the drama of medical progress. Scientists have discovered so much and the application of their discoveries have complicated medicine so that specialization has developed. For a long time physicians combined the art of general practice with the practice of a specialty. But with the great advances in medicine and science we have come to realize that major surgery is a complex procedure, requiring not only a knowledge of technique but a sound understanding of the principles of anatomy, physiology, pathology, chemistry, and physics.

In the past special training was obtained largely through the personal initiative of the physician

A period of study abroad was considered necessary and Paris, Berlin, and Vienna were popular mecca for medical students. Courses were given in this country by certain postgraduate schools, but with the exception of the one at the University of Pennsylvania established in 1919, these courses were largely short in duration and rarely satisfactory. Most surgery was taught by the preceptorial method. The younger men became associated with established surgeons as assistants and gradually learned the technique of surgery. As the technique of surgery became magnified, it was realized that the training of the general surgeon and the surgical specialist would require more time and effort on the part of the individual. For many years there have been opportunities for surgical training in the medical school hospitals and in a few other institutions, but it was becoming apparent that the need for training exceeded the good available opportunities. The College realized that in its hospital standardization surveys it had the machinery to increase the opportunities for graduate training in surgery and the surgical specialties. The subject has received the continuous consideration of the Board of Regents since 1930 and several committees have studied the problem in its relations to the requirement for fellowship. During the past three years the committee on graduate training in surgery and the field staff of the College have done a great piece of work and we can announce that 200 hospitals and other medical institutions are participating in approved plans of graduate training in general surgery and the surgical specialties at the present time.

It is interesting to philosophize on the question as to what is a surgeon. In his presidential address read before the American College of Physicians last April, Dr O. H. Perry Pepper attempted to answer the question, "What is an internist?" He found himself involved in a quagmire of words and meanings and definitions and finally concluded that

"an internist is a physician fitted by sound and applicable knowledge of the basic sciences, continued training in clinical medicine, familiarity with fields outside his own, and an intellectual, rather than manual or technical, approach to study, diagnosis, and treatment of the diseases of the field of internal medicine to which he strictly limits himself and to integrate with the knowledge of his own field that of the allied specialties.

With some change in phraseology this definition might define the surgeon. Much of surgical procedure is done and rightly so, by the general practitioner but a borderline is soon approached when the performance of a major operation on the

brain, the chest, the abdomen or the extremities involves not only manual skill but also a knowledge of anatomy, pathology and the other basic sciences together with a group of the increasingly difficult problems of pre-operative and postoperative care. The surgeon therefore, cannot be a general practitioner. He must have time to read, to study and to observe the work of other surgeons and unfortunately cannot cultivate the personal and family psychology of the patient as can the general practitioner to whom he is consultant and ally.

The formation of the boards of certification has influenced the desire for residencies, and the trend of present opinion is that such a residency is necessary for adequate training in surgery.

"There is gentle irony in the fact that men who to large extent are self-taught believe that their successors cannot achieve an education in the same manner."

One of the problems of the future should be a study of the effect of prolonged residencies on medical education on hospitals, and on the practice of medicine. This movement is formulating

very difficult problem for the hospitals because much of their organization must be dislocated in order to accommodate the new and important links between the interne group and the visiting group. Staff members and boards of trustees must be convinced of the importance of the residency and must be persuaded that sacrifice may be necessary to make it effective. The senior visiting staff must assume a preceptorial attitude and regard themselves as graduate professors of surgery. The junior visiting staff is in danger of being squeezed out from above and below unless the adjustment is made so that they also take part in the training plan.

In due time the new system will produce more highly trained men. A present day problem as well as one for the future is to formulate methods or backgrounds that will enable the individual trained in the residencies for two, three, or four years to adapt himself to competitive medical practice. As the *New England Journal of Medicine* states, these men will start with a strong tendency toward group medicine rather than toward individual practice.

I think that now I have said enough and really have said little but perhaps have offered some points for analysis. In 1874 Sir John Erichsen stated that "the abdomen, the chest, and the brain would be forever shut from the intrusion of the wise and humane surgeon. Unlike Lister he failed to envision the effect of Pasteur's germ theory upon the surgical operation. The researches

in chemistry today seem to us to be revolutionary in their effect upon the treatment of disease, but our sons and our grandsons will develop other ideas which will be thought to be the extreme in modern methods. Unlike Erichsen, we must not

exclude any lesion or organ as immune from surgical attack. And then we might look forward to the time when medical science has progressed to the point when all surgery of a destructive type can be abolished.

MEDICINE IN THE NATIONAL DEFENSE PROGRAM

IRVIN ABELL, M D, F A C S, Louisville, Kentucky

SINCE the members of the American College of Surgeons, with the exception of the Canadians present, are practically all members of the American Medical Association, I felt that you would be interested in knowing of the work of its Committee on Military Preparedness. This committee was appointed at the session of the House of Delegates in New York in June following a request of the Surgeons General of the Army, Navy, and Public Health Services that the American Medical Association undertake a survey of the profession of the United States regarding the qualifications and availability of its members for service.

There are 179,000 doctors entitled to practice in the United States by means of legal registration, and a questionnaire was sent to each of these. Between 140,000 and 145,000 are in active practice, while the remainder have retired because of age, disability, or their having sought other pursuits. So far 115,000 replies have been received, of which over 50,000 have been transferred to punch cards. These punch cards contain the information furnished by the questionnaires and by using them in the International machine, one may in a few minutes get a list of men qualified in any branch of medicine. This work has been undertaken by the American Medical Association as a patriotic contribution to the National Defense Program and has entailed the employment of an additional sixteen persons in the American Medical Association office. It is hoped that within two or three months information will be at hand upon every doctor in the country. The only exemption in the Selective Service Act applies to students of theology and accredited ministers of the gospel. Deferments will be made to students in accredited schools, pursuing a course of study leading to a degree in

Arts and Sciences and also to those who occupy essential positions in their community. In order effectively to safeguard the health of the population and to furnish medical service to the armed forces, the medical profession feels very strongly that medical students should be permitted to finish their undergraduate education and, at least, one year of internship before being inducted into service. The Selective Service Act, however, provides deferment for students only until June, 1941, after that date any deferment granted to medical students, to internes, and to residents will be the responsibility of the local draft boards. While doctors should be willing to make such adjustments as may be needed in the event of an emergency, it would be unfortunate if in the defense program the classes of medical schools, the teaching program of medical schools, and hospital service should be disrupted by an undue number of students, of internes, and of residents being called into service. This can be avoided only by applying to the local draft boards and to the appeal boards for the deferment of those essential to these three activities.

There are approximately 15,000 members of the Medical Reserve Corps and these will be largely drawn upon to furnish medical service for the first increment of selectees. It is estimated that by July, 1941, the total strength of the Medical Reserve Corps will be approximately 1,400,000 members and of the services of 10,000 doctors will be required. The length of service of the vast majority of doctors will be one year, at the end of which time they will be transferred to the Medical Reserve Corps on an inactive status. The information being gathered by the Military Preparedness Committee of the American Medical Association will make it possible to employ the services of doctors in position for which their training and qualifications fit them, and thus to avoid some of the mistakes and misfits of the First World War.

The major objectives of the survey are to provide medical service for the armed forces, to provide medical service for industrial mobilization, and to provide continuing medical service for the civilian population. In the first World War more than 32,000 physicians voluntarily served with the armed forces. In the event of war coming to our country again the profession will similarly give of its members a sufficient number to meet the needs of the Army, Navy, and Public Health Service. Furnishing medical service to the rapidly expanding industrial plants presents many difficulties. It will be no task to supply doctors who are fully competent to care for industrial injuries, but it is quite another problem to supply doctors familiar with the toxicological problems of industry. Practically all of the metals, many of the solvents, benzol, toluol, and many chemicals used in industry are capable of producing rather disastrous toxic effects upon the human organism. To control these hazards effectually requires the co-operation of the physician who is familiar with the problems and the safety engineer who understands methods of prevention. Continuing the service to the civilian population through hospitals and through men in various fields of practice is essential if the health and welfare of the civilian population is to be protected.

On September 19 President Roosevelt appointed a Health and Medical Committee a sub-committee of the National Defense Council. Its mem-

bers are Surgeon-General Magee of the Army, Surgeon-General McIntire of the Navy, Surgeon-General Parran of the United States Public Health Service, Dr. Lewis H. Weed, chairman of the Division of Medical Sciences of the National Research Council, and your humble servant, representing the civilian profession. The duties of this committee are to advise the National Defense Council on health and medical matters affecting National Defense and to co-ordinate all health and medical efforts. The medical division of the National Research Council has at present 38 committees, each studying some problem in its relationship to military medicine, such for instance as shock, chemotherapeutic treatment of wounds, blood transfusion, aviation medicine, tuberculosis, neuropsychiatry, nutrition etc. The Health and Medical Committee has appointed sub-committees on dentistry, medical education, hospitals, nursing, industrial health and medicine, and negro health. In all of this work an effort has been made to secure the advice and help of those whose qualifications in their respective fields entitle them to serve with advantage to the country.

It gives me much pleasure gratefully to acknowledge the unanimous offer on the part of the profession at large, of the various national and special medical societies, of the hospital groups, in fact, of all agencies relating to health and medicine to co-operate fully and freely in the defense program.

THE CIVILIAN SURGEON IN WAR

Brigadier General RAYMOND F METCALFE, M D , F.A.C.S , Washington, D C

BEFORE proceeding with a discussion of conditions in the Army which the civilian surgeon would encounter in the event of a general mobilization, I should feel remiss if I failed to pay tribute to the brilliant accomplishments of a few of our Army medical officers. Major Walter Reed and his associates showed us how to control and practically eradicate yellow fever. Colonel F F Russell, encouraged by Surgeon General O'Reilly, with great persistence and hard work secured volunteers to submit to antityphoid vaccine, proving it worthy as a preventative, and thus typhoid fever was practically eliminated from the Army where formerly it took a greater toll of death than battle casualties. There are many young medical officers in the Army today who have never seen a case of typhoid fever. Surgeon General William C Gorgas, through his knowledge of sanitation and prevention of yellow fever and control of malaria, made possible the construction of the Panama Canal. The work of Colonel William L Keller in the first World War on empyema cases following wounds and pneumonia is the real basis for all the brilliant present day thoracic surgery. Colonel Keller contributed another important contribution to war time equipment—the "Keller half ring splint," which has completely replaced the Thomas splint in the Army. The Keller splint is reversible and can be used on either right or left leg. After the splint has been padded, the damaged leg is laid in it and the half hip ring is completed to a full ring by a strap. The Thomas splint with a full hip ring can be used only on one side, thus twice as many splints are required. They are much more awkward to store and transport, are more difficult to apply as the injured foot and leg have to be passed through the ring, thus causing unnecessary manipulation of fractured bones.

From the Surgeon General's Office U S Army
Presented before the Clinical Congress of the American College
of Surgeons Chicago October 21-25 1940

Since this paper was written, early in August, 1940, a considerable portion of the National Guard has been mobilized for defense of the United States. Usually the Guard is called by regiments and the medical officers and enlisted men of the medical department are included. If one million men are mobilized by the selective draft that means seven thousand medical reserve officers will be called for service.

Many of the medical men here served with the Army during the first World War and are familiar with service conditions, and while we all hope that war will not be forced upon us the best insurance against such an event is a well trained and equipped army. I do not believe we will have to maintain a regular army of two million men permanently. Yet, we should have five to ten million men trained in the use of small arms and field guns, airplane pilots, tank drivers, machine gunners, signal corps men, and trained x-ray, laboratory, pharmacy, and dental technicians, as well as men trained in administering first aid.

The only way this can be accomplished will be by the establishment of a selective draft or universal service. The latter is the more equitable method. Every youth from 18 to 21 years of age, physically qualified, could, with advantage to himself and the Government, give 1 year to the Army, Navy, or Marine Corps, and thereafter for a determined number of years serve 14 days yearly with the colors.

If you could observe some of the recruits—awkward, with ungainly walk, round shouldered, and with faulty and unsanitary habits—after a 6 weeks' training period change into upright, alert, self-reliant, and well disciplined young soldiers, I am sure you could not offer a legitimate objection to the selective draft or universal service. Their improved health and physique more than offset any interruption to education, their improved physical condition and response to discipline work to their benefit throughout life. After a few years of

this training, with the spirit and intelligence of the American youth, it would be a bold people who would start trouble with the United States.

The younger medical officers assigned to duty with troops must remember that most of the recruits and draftees face a complete change in their mode of life. Their army life is regulated and the change in their habits is very marked. They are awakened by a bugle call, have a very short time to wash, shave, make up their beds, take a setting up drill, go to breakfast shortly afterward, are called to drill again, and this routine continues during the day. At night they are summoned to quarters with a call for lights out at 9:00 P.M. With this regulation of his life the recruit may neglect the calls of nature and feel ill. The sergeant puts his name on sick book and when sick call is sounded he and others of his company are marched to the doctor's office at the dispensary or hospital. With a large number of recruits, 50 to 100 men may have to report to the medical officer whose duty it is to see each man and find out his complaint. The sergeant, of the medical department, is instructed by his superior officer to take temperatures when indicated, to examine an injury or otherwise take care of the men. To many a dose of salts will be prescribed to some a cough mixture, and these recruits will be marked "duty." Some will be detained until the doctor can examine their abdomens, since by change of habits many men become constipated, we must always be suspicious of appendicitis and must not give cathartics when a man has pain in the abdomen. Again, the chest must be examined, and it must always be remembered that, with recruits from country districts especially measles, mumps, and meningitis must always be watched for and the men isolated in the hospital, for it is better to isolate them on suspicion of an infectious disease than to wait for many others to be exposed.

The line officers and drill sergeants who are responsible for the efficiency and the discipline of the recruits often speak sharply and with a good intentioned oath. Sometimes the new medical officer tries to emulate his brother officer of the line thinking the recruit is

malingering and often the new soldier is not seriously ill, just tired, a little constipated, and homesick. The medical officers should be firm but kindly. A little sympathy and friendly advice will help a lot. If there is any doubt of illness, better err by sending the man to quarters or the hospital for a day than to wait until he becomes seriously ill. Remember the medical officer and the chaplain are the only officers who can show a little sympathy for the new soldier without lowering discipline. Also remember that, with large concentrations of men, measles is often the first serious condition, followed by pneumonia, then empyema. This disabling sequence may be stopped by prompt isolation of the measles patient.

The American Medical Association has rendered a splendid service by card-indexing the physicians and surgeons of this country with their specialties and qualifications. This index will enable your Government to call on those needed for various assignments. It is often a hardship on a medical man temporarily to leave his practice yet it will be necessary for all of us to help the Government maintain itself and I am sure no American born or any adopted by America would care to give up his privileges and opportunities to lead the life he has chosen for that of a totalitarian form of government.

In war the country is divided into zones. That portion where fighting occurs, both land and water is known as the combat zone. Behind this section, where supplies are brought forward and wounded taken back, is the zone of communications, and farther back, the zone of the interior where conditions are more or less normal except for the busy factories making supplies for the Army recruiting, and distributing supplies and caring for the sick and wounded.

The first medical installation in the combat zone where the wounded may receive medical attention is the battalion aid station. This is close behind the firing line. Here, the battalion surgeon with meager equipment can apply a splint to a damaged arm or leg, give a hypodermic of morphine, antitetanic serum, apply a tourniquet and a moderate sized dressing.

Behind the battalion aid station are 3 collecting companies, each with 1 medical officer and 31 litter bearers. The non-ambulant wounded are carried by litter to the collecting station, preferably located behind a ridge or behind wooded land, where they will be protected from direct gun fire. To this point the ambulances proceed and take 4 litter patients or 2 litter and 6 sitting patients per ambulance. The ambulances take their patients to the clearing station, here are 6 medical and 1 dental officer with 95 medical department enlisted men. Also, there is a moderate equipment of field operating tables, medical chests of dressings, instruments, splints, equipment to furnish hot drinks, warm blankets, intravenous fluids. There is also equipment for such emergency operations as removal of hopelessly shattered arms and legs, removal of tourniquets and ligating vessels, application of more substantial splints to fractured arms and legs, removal of cloth or foreign material from sucking chest wounds, suture of the skin and fixation with adhesive straps, adjustment of bandages, suture of gaping abdominal wounds and, if the bowel is perforated, exteriorization of the loop and the application of dressings.

This station is equipped with the following anesthetics: inhalants, ether, intravenous, pentothal sodium, infiltrating, procaine and novocain, local, cocaine for eye and mucous membrane.

The commanding medical officer will have to estimate the patient's condition and decide where he is to be evacuated. At this time I wish to mention the work in 1936 of Major Sam Seeley with Drs. Essex and Mann (1) of the Mayo Clinic. When animals were given ether anesthesia and the peritoneal surface of the bowel was irritated by rubbing with gauze, they went into shock in 3 to 3½ hours. When these animals were given pre-operative sodium amytal, shock was delayed 10½ hours. We have observed in our spinal anesthetics, which are all preceded by sodium amytal or nembutal, that we rarely have a shocked patient. With this observation and the result of the animal experiments mentioned, we recommend that the battalion surgeons and hospital corps men be equipped with sodium

amytal capsules 0.2 gram and 1 capsule be given to every seriously wounded soldier before he is started to the rear. If shock is delayed 10 to 11½ hours, the safe evacuation by air or ground ambulance to fixed hospitals in the rear will mean the saving of many lives. Even shocked patients will not recover unless their surgical conditions are corrected. The next station is the evacuation hospital. Here débridements and all type of regional surgery can be done. If a patient can stand ambulance transportation, he should be sent to the evacuation hospital. For the more seriously injured the ideal method of transportation from the clearing station will be immediate evacuation by motor ambulance to a landing field, thence to the base or general hospitals in the zone of the interior by airplane ambulance. A dying man should not be removed from the clearing station.

Translation of "Casualty Evacuation by Airplane" in the Army Medical Bulletin No. 53 (2), based on German experience in Poland, is interesting, as it is probably the first time that battle casualties have been evacuated by air. Lieutenant General Erich Hippka, surgeon general, German Air Force, reports that 2,500 patients were evacuated by plane from Poland to hospitals in Berlin and elsewhere.

Ordinary commercial passenger planes were used. The plane is easily arranged for litter transport by straps and brackets to steady litters. An experienced medical officer in charge and available oxygen is required. The recumbent position lessens danger of air sickness, this rarely occurs under an altitude of 1,000 meters and if greater altitudes are necessary, oxygen relieves. No prolapses of organs or marked disturbances of peripheral circulations were reported. A final opinion of transportability of thoracic injuries was not rendered. Brain and face wounds, eye injuries and shattering wounds of spinal column, pelvis, and extremities were particularly favorable for air transportation *before* operation. Dysentery and typhoid patients were transported by air to home hospitals. Motor ambulance transport is necessary at the front and the home base to and from landing fields. The return journeys of the planes carried sera, medicines, and required equipment to the

front. Of the 2 500 evacuated by plane only 4 patients died in plane or immediately after landing and these planes were not staffed by medical officers. The speed of the ambulance planes was maintained at around 144 miles per hour. All planes were in radio contact with a directing center. The rapid evacuation by airplane had a splendid psychological effect on the wounded.

The medical officer at the clearing station has another difficult problem to decide as many men with minor injuries and feigned illness will drift back to this station. A dressing a hot drink or stimulant, and a short rest will straighten out this patient and then he must be sent to join his fighting companions. The surgeon must be firm and decide as battles are not won by evacuated soldiers.

The evacuation hospital is equipped for all types of emergency surgery and staffed with operating teams assigned to regional surgery, as thoracic, abdominal, cranial and neural orthopedic, genito-urinary and plastic maxillofacial. All the usual anesthetics can be supplied at this hospital. During and after a battle relieving teams, working night and day care for a large number of wounded. These hospitals are located at a railroad or on a waterway and evacuate the sick and wounded as soon as patients can be safely moved to the fixed base and general hospitals in the zone of the interior.

An interesting report from England in the treatment of wounds of the extremities is that the wounded extremity is carefully debrided sprinkled with sulfanilamide crystals, bandaged and the extremity put in a plaster cast the patient is evacuated and the cast is not disturbed so long as the patient's condition is satisfactory. The results so far reported are excellent. This treatment should be instituted at the evacuation hospital.

One of the newer developments of the medical department is the trailer hospital which was constructed under the supervision of Colonel Garfield McKinney, MC at the Field Service Laboratory at Carlisle Barracks, Carlisle, Pennsylvania and at the request of Colonel McKinney the surgical staff at the Walter Reed General Hospital and I planned the equipment.

The trailer operating room (Fig. 1) has floor space 11½ by 7½ feet storage space the forward part for instruments, anesthetics, drugs, etc. a scrubbing sink an instrument sterilizer ample ceiling light facilities double plate glass windows each side walls and ceilings insulated with 2 inches of cork zero heating and cooling equipment, and 120 gallon water tank in the forward part.

In supplying the instruments, the various specialists at the hospital were asked to select necessary instruments and omit unnecessary types. We selected a basic set with which most general surgical operations can be done. Then we selected supplemental sets to cover the regional operations. The supplemental sets are abdominal thoracic ear nose and throat eye orthopedic genito-urinary and scope and cranial and brain. There are basic sets and 1 each of the supplemental sets with each trailer operating room. These basic and supplemental sets will be furnished to all Army hospitals. At the base and general hospitals, power driven instruments for orthopedic and skull cases will be furnished to supplement the basic sets and, of course, types of anesthetics will be available.

The anesthetics for the trailer operating room are the less bulky types. Inhalant ether, spinal, novocain, nupercaine, spinal, cocaine and pontocaine local infiltrating procaine cocaine for eye conditions rectal avertin. The Heidbrink Gas Machine Company working with Captain William H. Nichol of the Medical Corps, has developed a small compact gas machine to supplement avertin and spinal anesthetics. Due to the rather small space a large machine and tank will be in the way and there is some doubt to the feasibility of a continuous supply of gas tanks. It is estimated that with 3 operating teams, 20 major operations can be done 24 hours in each trailer operating room. The trailer operating room will be accompanied by a sterilizer trailer a kitchen trailer and power plant for electric current.

During use the trailer operating room is backed up to an opening in a receiving tent. When all the casualties have been operated upon the trailers can move on to other fields, while doctors and nurses sent

Fig 1 Ambulance unit with interior view (Reproduced through courtesy of Army Medical Museum)

from the rear take over the now immobilized hospital, and the mobile units proceed to other localities

At the Army Medical Center in Washington, D C, we have a professional service school where all recently commissioned medical officers are sent for a 4 months' course of training in the principles of sanitation and preventative medicine, bacteriology and laboratory methods, and clinical instruction in orthopedic surgery. On completion of this course they are sent to the Medical Field Service School at Carlisle Barracks, Pennsylvania, where they receive 5 months' training in field work, practical sanitation, removal of wounded from the field, proper methods of preparation of patients for litter and ambulance transportation, and instruction in the handling of field hospitals and ambulance companies. On completion of this course they are ordered to various posts and general hospitals and have an opportunity to put to practical use the knowledge gained.

These young medical officers come from all parts of the United States, are graduates of reputable medical schools, and have interned in the best hospitals of the country, a fixed number each year apply for an internship in some of our general and large station hospitals of the Army. Each man accepted is recommended by the dean of his college and reports to the specified hospital on June 30. The

internship, when completed, gives him the necessary credits for his graduation. During their internships these young doctors receive board, room, and 60 dollars a month. At the completion of their internships and if recommended by the Medical Board, they are offered a commission as First Lieutenant in the Medical Corps of the Army. We secure many fine medical officers in this manner.

The Surgeon General, from time to time as vacancies occur or an increased quota of medical officers is authorized, announces dates for examination for commission in the Medical Corps. Examinations are held at various Army posts throughout the United States. Our physical examinations are very exacting as we hope each officer accepted will be physically qualified for at least 30 years' service.

During recent meetings in Washington, D C, under the direction of the National Board of Research and the Surgeon Generals of the Army, Navy, and Public Health Service, well known physicians and surgeons called from all parts of the United States have started an intensive study of the better methods of treating battle casualties and handling respiratory and other infectious diseases. Dr Evarts A. Graham is the chairman of the general committee and each member of the general committee is the chairman of a subcommittee for study of the

various types of regional surgery anesthesia, chemotherapy etc. Each committee is getting together in manuals all data covering the best method of treating the region wounded, and in the event of war these manuals will be published in a concise form to outline the better procedures, so that a young surgeon may quickly review and follow them.

An example in the plastic maxillofacial manual would be *don't remove loosely attached bone fragments* Support jaw with bandage and put an airway through the mouth. *Don't remove lacerated skin or muscles* Save it for the plastic surgical team at the evacua-

tion or fixed hospitals. Other manuals will give similar types of information. It is desirable that these manuals be of pocket size and on one page the *do's* and *don't's* summarized.

In conclusion may I say that if any of my statements help the junior medical officer in finding his place in the Army I shall feel well repaid.

THE NATIONAL RESEARCH COUNCIL COMMITTEE ON SURGERY

A Brief Statement of Its Work

LEWIS A. GRAHAM, M.D., F.A.C.S., St. Louis, Missouri

ANYONE who recalls the confusion and the hysterical haste which were conspicuous features of the medical preparations of the last war will doubtless be relieved to learn that if war comes this time there will be a minimum of confusion. At the time of the last war practically no medical preparations were made until after we were actually engaged in the conflict. Now, however, active steps are being taken to prepare adequately the medical corps of the Army and Navy well beforehand.

To accomplish this preparation there has been a division of labor, and different tasks have been assigned to different organizations. I shall speak briefly of the National Research Council Committee on Surgery. First a few words about the National Research Council. In 1916, realizing that this country was likely to be drawn into the maelstrom of the European war, President Wilson organized the National Research Council to give to the Government such advice on scientific matters of various kinds as might be needed in a national emergency. Since the war the existence of the Council has been maintained. It consists of several divisions, of which one is that of the medical sciences, and it shares with the National Academy of Science the beautiful building at 21st Street and Constitution Avenue, Washington.

In May of this year, realizing that again the nation was confronted with the possible danger of war, the Surgeons General of the Army, the Navy, and the Public Health Service called upon the National Research Council for advice regarding the newer ideas on the prevention and treatment of shock and on the applicability of the newer chemotherapeutic drugs to war infections. The chairman of the Division of Medical Sciences, Dr. Lewis H. Weed, accordingly appointed some committees to investigate the particular problems. It was soon realized, however, that the advisory work should have a much wider scope than that upon which the original work was undertaken. At the present time, in addition to

the two original committees on shock and on chemotherapy, respectively, there are three other major committees—one on surgery, one on medicine, and one on information. Of these major committees there are thirty subcommittees at work. The selection of the committees has been made after consultation with various civilian individuals and groups as well as with officials of the Army, Navy, and Public Health Service.

In order that there should be as little overlapping of function as possible the National Research Council's committees limit their activities to such fields as experimental research on problems that come up, matters of all kinds which concern the professional activities of the reserve medical officers personnel, advice on medical equipment and instruments, and in short anything with which the doctor as a medical officer is likely to be involved, aside from purely military or naval activities. As you know, the huge task of cataloging and classifying the medical profession of the country has been taken over by the American Medical Association. No other agency is so well equipped to carry out this function. We are fortunate that in this country at this time of peril to the nation there exists so efficient and powerful an organization able to perform this gigantic task of supplying to the armed forces of our country a list of experts available for every conceivable kind of medical work. The National Research Council Committee on Surgery is co-operating with the American Medical Association Committee to facilitate this work as much as possible. As a result of the careful evaluation and appraisal of each doctor's abilities, it is expected that there will be far fewer round pegs in square holes than in the last war. There will be no opportunity for any doctor, merely on the basis of wishful thinking, to be recognized by the army as a specialist. The committees which will scrutinize his record and assign him accordingly to his proper place will be guided only by his training and performance. Recently another much needed committee has been organized of which our own Dr. Abell is chairman. It has been recognized for several months that a committee to deal with all

Lectured before the Clinical Congress of the American College of Surgeons, October 21-25, 1930.

those affairs which will concern the health and medical activities of the civilian population in case of war should be organized as a part of the Council of National Defense, and recently President Roosevelt has appointed such a committee. Dr Abell himself will tell you more of this committee. I may say however in order to emphasize the harmony and co-operation with which the various medical preparedness committees are working that Dr Abell besides being chairman of this last mentioned committee is also chairman of the American Medical Association committee and a member of the National Research Council Committee on Surgery.

As examples of the sort of work that is being done by the National Research Council Committee on Surgery besides what has already been mentioned, it may be said that an extensive program of research on surgical infections is about to begin. Various pocket manuals of instruction of how to deal with different kinds of wounds are being prepared. Consideration is being given to the use of more protective armor than the steel

helmet. The most suitable methods of anesthesia for different kinds of operations and for use in different kinds of hospitals, together with the various types of anesthesia apparatus, are being discussed. Similar considerations are being given to the use of the x ray under the varying conditions of warfare. Many research projects are being given consideration, some of which will probably be set in motion soon. These are only some of the activities of that committee. We are not concerned with the granting of commissions in the reserve corps to any individuals except through our co-operation with the American Medical Association in the evaluation of the qualifications of individual specialists. We have however expressed the hope that the course of training of the young surgeons will not be seriously interrupted and that the work of the civilian hospitals will not be crippled by a wholesale removal of the house-staffs for military purposes. There is good reason to think that this hope which is shared by all who have an intelligent appreciation of the needs of the hospitals will be realized.

TWENTY-THIRD ANNUAL HOSPITAL STANDARDIZATION CONFERENCE

MALCOLM T. MACEachern, M.D., Chicago, Illinois

HOSPITAL Standardization is an exceedingly involved activity which nevertheless it is possible to crystallize in a single expression of its progress every year—the “Approved List.” The announcement of the list of 2,806 approved hospitals at the twenty-third annual Hospital Standardization Conference, held in Chicago in October, 1940, and its publication in the approval number of the *College Bulletin*, may seem to the uninformed observer to have been routine procedures, which have lost their stimulating effect because of the many regular repetitions. Instead, issuance of the list seems to acquire added significance each year, to judge by the repercussions that follow from the borderline hospitals which expected to be included but were not, and by the inquiries about how to meet the requirements some of which come from hospitals which were scarcely considered even as aspiring to approval.

Some things there are upon which steady hammering away with expression of ideals and the citing of examples creates an interest more substantial than that which is won by novelty. Hospital Standardization has earned a place in this category. Its influence has been cumulative. While it is true that a great many hospitals occupy an assured position on the approved list, that a doubt never arises about finding their names on it year after year, nevertheless even upon them the activity has a constantly stimulating effect because the fact of reconsideration for approval each year makes it necessary for them consciously to keep abreast of improvements in all phases of hospital work. Every year it becomes an unpleasant necessity to omit from the list some hospital from which protest is made on the sole ground that it has been approved for 10 or 15 years, and its facilities and methods are as good as they were when approval was granted. The answer to that protest is that the interpretation of the Minimum Standard is progressive from year to year, and that in the march of progress the hospital that is static falls farther and farther to the rear until finally it is behind the vanguard of approved hospitals and deserves no place in their ranks. Though a hospital has been twenty times approved, it has no assurance that it will be

approved the twenty-first year unless it is positive that in every respect it is up-to-date as of the current period in the advance of hospitals.

Of course, a great satisfaction in hospital standardization work is the handful of hospitals that are each year converted from the borderline condition to full acceptance of the standard. The satisfaction does not lie in being able to show an increase in the number of approved hospitals, but in making available to more patients the benefits of hospital service that is properly organized, controlled, and directed. Whenever a hospital is added to the approved list, the correct way to evaluate the gain is by the additional number of patients who are as a consequence receiving better care. Patients in the smaller hospitals and in hospitals in areas distant from the medical centers are especially in need of the assurance that they are receiving a high quality of care, and this assurance the approved hospital is entitled to give.

So far as the smaller town is concerned, Hospital Standardization has been a timely activity, coincident with a rapid general trend toward better distribution of the comforts, conveniences, safeguards, and luxuries of life. In a recent article in *Harper's Magazine* by Bernard De Voto on “Main Street Twenty Years After,” an excellent description is given of the way in which standardization has transformed the average town. Retail stores, schools, transportation and communication systems, power and light facilities, and sanitary precautions, have been immeasurably improved through standardization even in small villages. Hospital service should have kept pace with this advance, and it is the aim of Hospital Standardization that at least the same favorable comparison with facilities in the large cities be attained by the hospitals as by other public services in the smaller communities. Not all of the unapproved hospitals are by any means in the less populous areas, it is true, but so large a proportion of them are that the need there should be emphasized. De Voto says that standardization, “which so enraged the intellectuals of the 1920's, has in reality annihilated much that was deadening and disruptive in rural existence.” To which should be added that it has also annihilated

much that was distressing and dangerous, when sickness or accident struck, by making it possible for a hospital to give good service even when its capacity is as few as 5 beds.

Hospital Standardization is not only always reaching out to influence for good the below grade hospital but it is also working for better service to the individual patient in the approved hospitals. A hospital that readily meets the general standards for approval, may yet be ministering poorly to the needs of certain types of patients. These needs are discovered in the surveys and through contacts with hospital personnel who are aware of them and are brought up for discussion at the Hospital Standardization Conferences in connection with the Clinical Congress and sectional meetings of the College. An example was the conference on convalescent care at the Clinical Congress in October in which the needs of a number of different types of convalescent patients were discussed by specialists in each field. The keynote was set by the title of the address of the presiding officer, Dr. Harry E. Mock, of Chicago, "Convalescent Care—the Missing Link in the Cure of Many Patients." The special needs of the surgical, the medical, the cancer, the fracture, the orthopedic, and the pediatric patient were presented, respectively, by Dr. Donald B. Wells, of Hartford; Dr. Newell C. Gilbert, of Chicago; Dr. Frank E. Adair, of New York; Dr. Robert H. Kennedy, of New York; Dr. Frederick C. Kidner, of Detroit; and Dr. Louis A. Schwartz, of Detroit. Dr. Gilbert made a particularly salient point when he departed from the idea of "convalescence" toward that of using the convalescent home partly as a "preventorium," urging that hospitalization could frequently be avoided, with great economic saving, by preventive care in this type of institution. Dr. William H. Walsh, of Chicago, in describing the essentials in planning of institutions for convalescent care, said that surveys have shown that an average of 12 per cent of patients occupying beds for acute illness in hospitals are suitable cases for convalescent care, and remarked that "if and when adequate

convalescent facilities are made available, there will be a considerable reduction in the number of chronic cases to be provided for." Elizabeth G. Gardiner, of New York, in a talk on "Socio-Economic Aspects of Convalescent Care," urged the increased consideration of proper convalescent care as a means of more speedily returning the patient to his or her usual function as worker or housewife. E. H. L. Corwin, Ph.D. of New York, in discussing "Minimum Standards for Convalescent Hospitals," suggested that "with the oncoming national emergency it may be of great moment to be able to transfer to convalescent homes, hospital patients who have passed the acute stage of their illness or disability" and he therefore urged that the American College of Surgeons "duplicate the splendid work it has done in the hospital field by developing minimum standards for convalescent hospitals and supervising their adoption," saying that, after all, "the medical and surgical job is not completed upon the patient's discharge from the hospital."

It may well be that the needs of the national defense program as it concerns hospitals will indicate the desirability of more attention to the needs of the convalescent patient, and will act as a spur to greater development of facilities to serve him. The *Minimum Standard for Hospitals* is sufficiently elastic to provide a gauge of approval for the convalescent institution, and if after further study and investigation it seems desirable to formulate as a guide a special auxiliary minimum standard, this can readily be done as it was in the case of cancer clinics and of plans for graduate training in surgery in hospitals.

The Hospital Standardization conferences are valuable in bringing new needs to the surface and in enabling exchange of views with hospital personnel on current problems. They together with the personal surveys on which the approved list is based, keep Hospital Standardization close to the ground, broadening its scope to embrace developing needs, and making approval a practical, attainable goal for any hospital and a direct influence for better service to every patient.

THE 1940 CLINICAL CONGRESS

JOHN A WOLFER, M D , F A C S , Chicago, Illinois

SOME dominant note in response to a scientific development or a social need seems to ring through each Clinical Congress, and, as might have been expected, the 1940 Congress was tuned to the current interest in national defense. Though in only one session were the discussions predominantly centered upon the physician's rôle in military preparedness, nevertheless the additional incentive for research and experimentation, which preparedness gives, kept rising to the surface in the talks and comments at many of the meetings. A report on the work and plans of the committee on surgery of the National Research Council was presented by its chairman, Dr Evarts A. Graham, the new president of the American College of Surgeons, and the aims of the health and medical committee of the Council of National Defense to co-ordinate the efforts of all agencies working for medical preparedness were described by its chairman, Dr Irvin Abell, chairman of the Board of Regents, at the Wednesday evening session. Representing the medical corps of the United States Army, Brigadier General Raymond F. Metcalfe told of the correct attitude of medical officers toward draftees, and described some of the applications in military service of new developments in medicine.

The Surgeon General of the United States Navy, Rear Admiral Ross T. McIntire, brought to the attention of the public the plans for "Medical Preparedness for National Defense" in an address sponsored by the College over the National Broadcasting Company network on Sunday evening preceding the opening of the Clinical Congress. Introduced by Dr Abell, Admiral McIntire said in part:

"It is extremely gratifying to find the splendid co-operation that is being given to the Army and the Navy by such organizations as the American College of Surgeons. The work of the College in the industrial field of medicine is playing a most important part in plans for expansion in that field. The Army and the Navy will demand a great deal from the medical profession, the nurses, the hospitals, and all other allied organizations that have to do with health. We in the military services are being exceedingly careful not to rob our industrial centers, our small towns, and rural communities of proper medical and hospital care.

"This is being done by the preparation of a broad and comprehensive plan by which proper selection of personnel will be made in a rational manner."

Chairman of the Committee on Arrangements

Brigadier General Metcalfe gave a talk over the Columbia Broadcasting System network on Thursday evening of the Congress in which, following an introduction by Dr Graham, he told of a preparedness program, "not for war, but to prevent war," and assured the mothers of America that their sons, if called to military service, will receive "good food, warm clothing, healthful training, instruction in a particular branch of service, instruction in personal hygiene, and the best of medical care if sick or injured."

Particular mention is made of these broadcasts because of the omission from the 1940 Clinical Congress program of the heretofore customary community health meeting, and because the chairman of the arrangements committee is also chairman of the Committee on Public Relations and hence is immediately concerned with those aspects of the Congress which are of interest to the public as well as those that appeal to the profession. Through the co-operation of the public service divisions of the large broadcasting systems it was possible to convey to the public the timely messages of the Surgeon General of the Navy and the assistant to the Surgeon General of the Army.

The 1940 Presidential Meeting or Convocation was lacking, of necessity, in one feature to which we have become accustomed, the introduction of foreign guests, but in other respects was characterized by the usual impressiveness. The class of initiates received into fellowship was exceptionally large—there was a total of 611 new members—which brings the enrollment of the Fellows to well over 13,000.

The clinics in some forty of the approved hospitals in the Chicago area were exceptionally well attended, and again it was demonstrated how helpful it is to the individual surgeon to have the program so arranged that one who is interested in a specialty can if he wishes give almost undivided time to its study in the clinics and in the scientific sessions, panel discussions, and group clinical conferences. The clinical conferences were a new feature in 1940, and a popular one, with overflow attendance registered in many instances. The ophthalmologists and otorhinolaryngologists, in particular, expressed great satisfaction with the six conferences arranged for them on three successive mornings.

The symposium on cancer attracted the usual wide interest, and considered in conjunction with the announcement of the list of 345 approved cancer clinics in hospitals in the United States and Canada, and of additions to the archives of 5 year cancer cures which bring the total to 36,078 constituted one of the most important events of the Congress, indicating the concentrated effort that is being directed toward gaining better control of this disease.

Another outstanding session was the symposium on fractures and other traumas. This session, also should be evaluated against its background of intensive activity by the College, especially in connection with the treatment of fractures which has been improved largely through the efforts of the Committee on Fractures and the Regional Fracture Committees which the chairman of this meeting announced, now number 85 and have a total membership of 1,400.

The reports of the Committee on Cancer and of the Committee on Fractures and Other Traumas were presented in detail at the annual meeting of the Fellows on Thursday afternoon, together with reports of the Library and Department of Literary Research, the Department of Hospital Standardization, the Department of Clinical Research and others, giving an impressive picture to the Fellows of the great amount of activity bearing directly upon improvement of medical and hospital service in which the College is engaged.

As to new developments reported at the Congress, that in which there is probably the widest interest was the increasing use of the sul-

fonamides: one speaker told of the use of these compounds as aids to surgery and another described the rapid healing of wounds received in war or accidents when sulfanilamide was applied. Another interesting report was that the acute symptoms of Ménière's disease may be relieved by injections of histamine. The permanent cure of Ménière's disease by dividing the auditory nerve was reported in 401 operations, with only 1 death which was due to meningitis. The use of the anti-blood-clotting substance, heparin, in the successful grafting of pieces of veins to bridge gaps in wound-torn arteries was announced. The results of high voltage radiation therapy in gynecological cancer were reported.

The 940 Congress brought forth many new ideas in applying the scientific developments in practice in hospitals. The concurrent holding of hospital conferences serves to emphasize the important place of surgery in the hospital and the desirability of its strict control. It serves also to keep before the surgeon's mind the many services in the hospital, proper performance of which contributes to more successful surgery.

The surgeons of Chicago are proud to have been hosts to the thirtieth Clinical Congress, as they were to the first, held in 1910. Eight times our city has been the setting for this illustrious gathering. The medical schools and hospitals of Chicago co-operated generously in arrangements for the 1940 meeting, and the committee gratefully acknowledges their support and that of the individual speakers, leaders of discussion and collaborators, exhibitors, and all who in any way helped toward the success of the Congress.

FUTURE NEEDS FOR GRADUATE TRAINING IN GENERAL SURGERY AND THE SURGICAL SPECIALTIES

DALLAS B. PHÉMISTER, M.D., F.A.C.S., Chicago, Illinois

IN its program of graduate training in surgery the American College of Surgeons has proceeded on the theory that all hospitals, be they large or small, situated in metropolitan centers or in the smaller towns, are educational institutions in the truest sense when they follow the principles of hospital standardization. The medical school lays the foundation for the education of the physician, but the hospital erects upon that foundation the framework of practical training. In proportion as the educational rôle of the hospital is conscientiously planned and played, the physicians and surgeons who enter practice will be competent and trustworthy.

The medical schools alone, important and fundamental as their place is, can never produce surgeons sufficiently qualified to be entrusted with people's lives. Apprenticeship to an older practitioner is now less and less frequently employed as a method of training. Hence in our day the hospital, every hospital, must definitely assume its due share of teaching responsibility if the public are to be given the full advantages of progress in medical science. This is a never ending responsibility, not only in respect to the year by year entrance and outgoing of internes and residents, but in its application to the progressive education of every member of the staff. Even the hospital that has no internes or residents may so organize its staff that there is effective control by the more experienced members over those not so well qualified, and this is an educational function.

What the College hopes to do, and what it has already in some degree accomplished, is to heighten the consciousness of hospitals to their educational obligations and opportunities. The graduate training program is simply hospital standardization carried forward in one of its educational phases. Rather conspicuous proof of success in arousing a consciousness of educational responsibility was furnished by the publication in the October, 1940, *Bulletin*, of detailed descriptions of the plans for graduate training in general surgery and the surgical specialties of two hundred hospitals in the United States and Canada which have been approved for this purpose. Many hospitals have initiated graduate training pro-

grams, and others have amplified and revised theirs, as a result of encouragement by the College, and guidance which in the past year has taken tangible form in a published *Manual*, available now in reprint form under the same cover with the descriptions of the approved plans.

The growth in the number of hospitals participating in approved plans from 179 on October 1, 1939, to 200 on October 1, 1940, together with the increase in the number of men in training in general surgery and the surgical specialties from 1,606 in 1939 to 1,745 in 1940, shows the widening interest. There is also indicated a definite trend toward development of plans of graduate training of three or more years' duration in general surgery, as well as in many of the surgical specialties, that is significant. Of those completing work in general surgery in 1940, 73 per cent received three or more years' training.

A number of the hospitals whose plans for graduate training in surgery have been approved are a part of universities and medical schools. Valuable as such direct connections are in facilitating study of the basic sciences, a lack of them and also of sufficient and varied clinical material can be surmounted by affiliation with some medical school and by co-operation with other hospitals. So thoroughly convinced is the College by its experience with this program that the standards of surgical performance in a hospital are almost automatically raised when it undertakes to provide graduate training in surgery, that the theory upon which future work will be based is that reasonably wide participation is eminently desirable, and encouragement and help will continue to be given the hospital which establishes affiliations in order to furnish a well rounded program.

Better distribution of thoroughly qualified surgeons is the great need, and an obvious way of helping to effect this is to have surgical training centers more widely distributed. Some of those who complete their training in districts away from the leading medical centers will remain there to practice, and not only the institutions definitely organized for teaching but others in the vicinity as well, will benefit ultimately by having better surgeons on their staffs. The cycle of benefits will

Chairman of the Committee on Graduate Training for Surgery

be advanced by the attraction of surgeons trained in the medical centers, to the improved hospitals in the less populous areas.

It is a long view that the College is taking in the graduate training program—a view that yields no prospect of a goal possible of complete attainment. To the argument that enough surgeons are being trained now to fill the need in numerical terms, the conclusive answer is that not all of these surgeons are being trained well enough, nor are there likely to be too many well trained surgeons, at least in the generations immediately ahead of us. For medical schools a curriculum can be established, adherence to which forms the basis of approval for hospitals so many intangible factors are involved in addition to provisions for basic science study and supervision, that constant and continuous work with them is essential to progress. This is especially true in view of the fact that, after all, the teaching function is subordinate to the chief purpose of serving the patient and is worthy of promotion only because

when properly carried out, it contributes to improvement in that primary aim.

The program is an integral part of the purpose of the College to elevate the standards of surgery. It is notable for interpreting that purpose to mean that the standards should be elevated everywhere. Because the need for better surgery is greatest in that type of institution the keenest satisfaction is felt when the heretofore "non-teaching" hospital assumes teaching and training responsibilities as meets the requirements for approval. The College has closely at heart the welfare of patients in all types and sizes of hospitals and is constant in striving for higher standards of training for surgeons and better control of surgery.

Hospital standardization and graduate training for surgery as well as for all other branches of medicine, should progress hand in hand. A hospital of the requisite bed capacity should be recognized as possessing adequate standards which does not also conduct a program for adequate training for surgery.

CRANIOCEREBRAL INJURY

ALFRED P. ROWLAND, M.D., F.A.C.S., and DAVID O. WEINER, M.D., St. Louis, Missouri

DURING the period of 1934 to 1937 inclusive, there were 634 cases of severe craniocerebral injury and 604 cases of concussion admitted to the St. Louis City Hospital. All deaths were included under the heading of acute craniocerebral injury and the mortality of this group was 38.9 per cent. This checked closely with the last report from Bellevue Hospital of 37.8 per cent (12).

However, it compared quite unfavorably with reports of Fay, Mock, Swift, Munroe and others of mortality rates varying from 17 to 26 per cent. Although some feel that institutions receiving all the patients with severe trauma from the street accidents of a large city will naturally experience a higher mortality than will the private hospital, we could not help but feel that this discrepancy was too great.

At this hospital due largely to the influence of Sachs, spinal puncture was rarely used as a therapeutic measure and only infrequently as a diagnostic measure in cases of craniocerebral injury. Hypertonic sucrose and dextrose intravenously and magnesium sulphate as retention enema were the two dehydrating measures which seem to have been usually used. Little cognizance had been paid to the limitation of fluid intake as advocated by Fay in the treatment of these cases.

Transcribed from the original manuscript

The use of hypertonic solutions intravenously as dehydrating agents seems to be universally accepted, except by Dandy, who feels that both of these measures are contraindicated in these cases.

The limitation of fluid intake does not seem to be as popular as the use of spinal puncture and dehydrating agents, at least it does not receive the important position in the therapy accorded the two other measures.

Since the cases of intracranial injury were admitted to two distinct staff units it was felt that we were in a position to evaluate these procedures in the therapy of severe intracranial injury. One unit which we shall designate as Unit A was opposed to the use of lumbar punctures as a therapeutic measure and during the first year did not actually restrict the fluid intake. Although sucrose intravenously was used on both units its use on Unit A was restricted as compared with its use on Unit B.

The visiting surgeons of Unit B consulted and agreed to the study which we termed "active dehydration" following basically the ideas as expressed by Fay (4) comprising (1) lumbar punctures, (2) intravenous injections of 100 cubic centimeters of 50 per cent sucrose and limitation of fluid intake.

Regarding the difficulty of ascertaining the treatment of intracranial injury because of the fact that these patients are

CRANIOCEREBRAL INJURY

AVERY P. ROWLETTE, M.D., F.A.C.S., and DAVID O. WINNER, M.D., St. Louis, Missouri

DURING the period of 1934 to 1937 inclusive, there were 634 cases of severe craniocerebral injury and 604 cases of concussion admitted to the St. Louis City Hospital. All deaths were included under the heading of acute craniocerebral injury and the mortality of this group was 38.9 per cent. This checked closely with the last report from Bellevue Hospital of 37.8 per cent (12).

However, it compared quite unfavorably with reports of Fay, Mock, Swift, Munroe and others of mortality rates varying from 17 to 26 per cent. Although some feel that institutions receiving all the patients with severe trauma from the street accidents of a large city will naturally experience a higher mortality than will the private hospital, we could not help but feel that this discrepancy was too great.

At this hospital due largely to the influence of Sachs spinal puncture was rarely used as a therapeutic measure and only infrequently as a diagnostic measure in cases of craniocerebral injury. Hypertonic sucrose and dextrose intravenously and magnesium sulphate as retention enema were the two dehydrating measures which seem to have been usually used. Little emphasis had been paid to the limitation of fluid intake as advocated by Fay in the treatment of these cases.

The use of hypertonic solutions intravenously as dehydrating agents seems to be universally accepted, except by Dandy who feels that both of these measures are contraindicated in these cases.

The limitation of fluid intake does not seem to be as popular as the use of spinal puncture and dehydrating agents at least it does not receive the important position in the therapy accorded the two other measures.

Since the cases of intracranial injury were admitted to two distinct staff units it was felt that we were in a position to evaluate these procedures in the therapy of severe intracranial injury. One unit which we shall designate as Unit A was opposed to the use of lumbar punctures as a therapeutic measure and during the first year did not actually restrict the fluid intake. Although sucrose intravenously was used on both units its use on Unit A as restricted is compared with its use on Unit B.

The visiting surgeons of Unit B consulted and agreed to the study which we termed active dehydration following basically the idea as expressed by Fay. At the present time lumbar punctures and intracranial injections of 100 cubic centimeters of 50 per cent sucrose and limitation of fluid intake are being fully the difficulty of carrying out the treatment of intracranial injury because of the fact that the patient is not

routinely seen and early treatment instituted by the resident staff it was felt imperative that rules of treatment and some sort of outline be set up for them to follow. Accordingly the following routine was established.

1. Unconscious patients were treated for shock if present. Lumbar punctures were not performed in the presence of shock. Intravenous sucrose was not considered contra-indicated in the presence of shock. It has been our impression that uncomplicated intracranial injury is not usually associated with profound shock. The usual treatment of shock was administered except for the use of morphine which was felt to be contra-indicated.

2. If shock was not present or had been relieved and the patient was unconscious, a lumbar puncture was performed. A water type of spinal manometer¹ was used to measure the cerebrospinal fluid pressure. Although we recognize that it is sometimes difficult to ascertain an accurate pressure, due to the straining of the patient, as a general rule we felt that reasonably accurate pressure readings were obtained. During the early months of this study if the pressure was markedly elevated, it was reduced to one-half of the original reading at the time of the first tap, and this procedure repeated every 4 hours until the pressure was brought to normal. After 3 months, experiencing no untoward results, we adopted the routine of immediately reducing the pressure to normal at the time of the original lumbar puncture. The house officers who performed the lumbar punctures were thoroughly warned of the potential dangers of the procedure in the presence of increased intracranial pressure and were very cautious to remove the cerebrospinal fluid *very slowly*.

3. If the cerebrospinal fluid was grossly bloody (not just turbid) the canal was slowly drained dry (i. e. fluid allowed to escape until no more spontaneously dropped from the needle) the amount of fluid being removed to accomplish this varied from 15 to 45 cubic centimeters.

4. During the first 3 months of the study if the patient remained unconscious, punctures were repeated every 4 hours. This period

was then lengthened to 6 hours, because we found that usually the pressure tended to stay level for about 4 to 5 hours if after each puncture 100 cubic centimeters of 50 per cent sucrose was slowly injected intravenously. Punctures were discontinued with the appearance of consciousness unless the fluid was grossly bloody in which case they were continued every 6 hours until the cerebrospinal fluid was grossly clear. Sucrose was ordinarily continued for one or two injections after the patient regained consciousness. If the patient remained unconscious longer than 48 hours, punctures were checked once daily to make certain the pressure remained normal, until the patient regained consciousness.

5. Fluid intake was limited to 1000 cubic centimeters whether by mouth or parenterally. If the patient was unable to take fluids by mouth, fluids were usually administered in the form of 5 per cent dextrose in Ringer's solution intravenously. If the patient remained unconscious longer than 48 hours, this was increased to 1500 or 2500 cubic centimeters per 24 hours.

The persistence of unconsciousness was the criterion used to gauge the necessity of continuation of the dehydration regimen. Lumbar punctures and intravenous sucrose were rarely necessary after the first 48 hours and fluid restriction could usually be lifted after the third day. If the patient developed a fever the fluid intake was increased and taps continued longer than the usual period.

Cases were divided into (1) acute craniocerebral injury and (2) concussion. All deaths occurring in the concussion group were included in the first group. All cases with demonstrable intracranial injury or skull fracture were included in this series regardless of how severe associated injury was present elsewhere in the body. All deaths which occurred (2 deaths) prior to admission to the hospital wards were excluded from this series.

In the first group we included (a) all cases with an obvious compound skull fracture or cases with positive x ray evidence of skull fracture (b) traumatic cases unconscious until death (c) cases presenting the general features of a basilar fracture, that is, ecchymotic orbital lids, aural bleeding, grossly

bloody spinal fluid, and (d) cases showing evidence of intracranial injury at autopsy

In the second group were included all cases ordinarily considered as concussions. Cases with a momentary or short loss of consciousness, following injury to the head, without symptoms of intracranial injury other than headache, nausea or vertigo, without grossly bloody spinal fluid and with negative x-ray evidence of a fracture of the skull were all included in this group. We feel that the inclusion of concussions in the statistics of some observers in the discussion of severe intracranial injury only clouds the issue and makes it impossible or difficult to compare results. We have made every effort to restrict cases in group 1 to severe injury, placing all cases, which were considered in group 2 until death, in group 1 in tabulating the results. Hence, we show no deaths under concussions. We had relatively more concussions than severe intracranial injury during the 2 year study period than we did during the 4 previous years.

ANALYSIS OF RESULTS

Of interest is a comparison of the etiological agents of this series and of one reported by Stewart from this hospital 20 years ago, in which he focused attention upon the tragic mortality attendant upon routine operative decompression in these cases. As predicted by Stewart, we have experienced a 25 per cent increase of severe craniocerebral injury almost entirely related to the automobile.

Because of the danger of herniation of the medulla and cerebellum into the foramen magnum resulting from spinal puncture in the presence of increased intracranial pressure, and because of the fact that in grossly bloody spinal fluids, we were draining the cerebrospinal canal dry and thus possibly inviting this complication, we were particularly on the watch for such findings at postmortem. Since in traumatic deaths, practically all victims are subjected to postmortem examination by the coroner, we were able to check our findings at autopsy in 88.8 per cent of the deaths of Unit A and 92.8 per cent of the cases of Unit B. In all deaths on Unit B in which spinal puncture had been used, postmortem examination was carried out in 100 per cent of these cases and

Graph 1 Total hospital mortality, severe craniocerebral injury

in no instance did we observe any evidence of medullary compression or "cone" formation. We feel that the constant use of the manometer and the *very slow* removal of fluid account for these results, because unquestionably this disaster may happen in intracranial injury (8), and we hazard an opinion that it may occur not only in cases with a block at the foramina of Magendie and Luschka, but in cases with a perfectly open system due to rapid removal of cerebrospinal fluid.

Mortality experience Graph 1 presents a summary of the total mortality experience for a 6 year period and the mortality of Units A and B during this study. During the year 1938-1939 in Unit A an excellent control series was available and it will be noted that the mortality on Unit B fell to 21 per cent which compared very favorably with the reports previously mentioned of mortality rates from 17 to 26 per cent. On Unit A, however, the mortality continued at approximately the average for the 4 year period preceding the study, that is, 37.3 per cent. During 1939-1940, due to a reorganization of the staff, the cases on Unit A were under different staff supervision, and approximately one-half of the cases had a limitation of fluid intake to 1500 cubic centimeters of fluid per day in addition to more widespread use of sucrose intravenously while the other half continued about as before. It will be noted that for this year the total hospital mortality fell to 28.5

Graph 2. Rapid relief of cerebrospinal fluid pressure with spinal drainage.

Graph 3. Delayed return to normal despite drainage.

per cent which was approximately 10 per cent less than the 4 year average mortality preceding the study or 38.9 per cent.

Cerebrospinal fluid pressure. Like Werden we found that our patients tended to fall into two groups one (Graph 2) in which there was a progressive fall in cerebrospinal fluid pressure which constituted the usual response, and the other (Graph 3) in which the pressure continued high, despite repeated spinal drainage, dehydration, and limitation of fluid intake. It is of interest that our curves are similar Werden apparently performing daily spinal drainage while we followed the same practice every 6 hours. In our cases the cerebrospinal fluid pressures generally reached normal limits in 48 hours, while he shows a like result in his graphs accomplished in usually 4 to 6 days. As has been noted by many observers, we found no consistent correlation between the clinical condition of the patient and the cerebrospinal fluid pressure. We found that many patients with severe intracranial injury and also suffering from severe shock usually occasioned by associated injury tended to have low cerebrospinal fluid pressures. Like other observers (2) we could not discern any consistent correlation between the patient's blood pressure, pulse or respiration and the cerebrospinal fluid pressure. Headache was usually relieved immediately by spinal drainage and although it was observed that intravenous hypertonic sucrose would often times accomplish this same result, its relief was much slower in appearance and much less prolonged.

Surgical intervention. The neurosurgery of all units during 1938-1939 and for all except

3 cases during 1939-1940 was supervised by the same neurosurgeons, hence no attempt is made to separate the statistics by units. During the 2 year period 1939-1940 there were 16 compound skull fractures debrided with 3 deaths, 2 simple depressed fractures elevated with no deaths, 13 patients explored for surgical bleeding, and of this group only 1 presented the picture about which we hear so much, of so called "middle meningeal hemorrhage"—the remainder presenting the difficult diagnostic problem commonly seen in severe intracranial injury. Of the 13 cases explored, hematomas were found and evacuated in 8, of these 4 survived. In 5 extensive brain injury with diffuse bleeding was found and none survived.

In the group A cases there were 6 at post mortem which showed large hematomas, but of this group all died within 3 hours after admission without presenting localizing signs except 1. In this instance because of advanced age and the absence of localizing signs, it was deemed inadvisable to explore. In group B likewise, 4 at autopsy showed similar findings, 3 of whom died within 3 hours after admission, and 1 died on the fourth day after a diagnosis of cerebral apoplexy inaccurately made largely because of inadequate history.

It seemed of significance to us that we did not experience any increase on Unit B of hematoma formation due to the complete spinal drainage of grossly bloody spinal fluid which was carried out as some contend that spinal drainage in the presence of bloody spinal fluid will only facilitate increased

bleeding In several patients we made a partial replacement of the fluid removed by air injection into the spinal canal, but we could not state that there was any apparent effect on the continuation of the bleeding. This has been suggested by Fay (5) as a possible aid in the control of traumatic intracranial bleeding.

RATIONALE OF TREATMENT

The rationale of this mode of treatment has been beautifully expounded by Fay (4), but it is difficult to correlate it with the observations of Browder and Meyers. We have continued the regimen because of improved mortality and our very definite impression that patients were benefited by the treatment. We are not convinced that any one of the three, i.e., spinal drainage, hypertonic agents or limitation of fluids, is most important or absolutely essential, but we feel that all three have their indications.

A properly performed spinal puncture gives important diagnostic and prognostic information, is of definite value in the relief of traumatic headache, and, judging by our results, of definite value in the treatment of these patients.

Although Gurdjian and his co-workers state "the intravenous administration of isotonic fluids did not cause any increase in the cerebrospinal fluid pressure in the great majority of their cases" and advocate the administration of 2,500 to 3,500 cubic centimeters of fluid by vein in patients with severe intracranial injury who remain unconscious for days, we feel that the restriction of fluid intake to 1000 cubic centimeters per day for the first 48 hours was of definite aid in the treatment of these patients. After that in the type of case mentioned it is advisable to increase the fluid intake to 1,500 or 2,000 cubic centimeters because continued dehydration may produce untoward reactions. By marked fluid restriction to 500 cubic centimeters for 2 and 3 days in a few cases, we have had an opportunity to observe the "dry tap" as a result as previously described by Fay (4).

Schwartz and Elman have shown that sucrose is not as effective a dehydrating agent as is sorbitol, and the use of hypertonic

Graph 4 Mortality of groups "A" and "B" by decades
A— B - - -

sucrose has been very recently questioned by Anderson and his co-workers, who found evidence of tubular damage in the kidneys after its use in patients with impaired renal function.

Unfortunately, in this regard almost all of these deaths were autopsied by the city coroner, who does not make routine microscopical examination of tissues, and hence sections of the kidneys are not available for review.

In 5 cases in which patients had received hypertonic sucrose autopsies were performed by the hospital pathologist, and Dr S H Gray states, "three of these showed marked swelling and vacuolization of the cytoplasm of the tubular epithelial cells. Nuclear changes were generally more markedly changed than the distal portions. Glomerular change was not noted except in a fourth case which showed general vascular congestion. In this case less tubular change was present. The patient who received the largest amount, 1,340 cubic centimeters of 50 per cent sucrose in the 96 hours preceding death, showed no renal lesion. The patient who received the smallest amount, 100 cubic centimeters of 50 per cent sucrose in the 24 hours preceding death, showed the most advanced tubular change."

Unless further observation shows that hypertonic sucrose produces the changes noted by Anderson in patients with normal kidney function, sucrose will probably continue to be used, since it is a valuable agent, easily and inexpensively prepared by the average hospital personnel.

SUMMARY

1 A study of 121 cases of severe cranio-cerebral injury in which spinal puncture by hypertonic sucrose and limitation of fluid intake were used in treatment is reviewed in this article.

2 A mortality of 23.1 per cent was experienced as compared with a previous 4 year mortality on this same unit of 36.7 per cent and as compared with a control unit (which used only hypertonic sucrose for 1 year and in addition the following year used limitation of fluid intake to 1500 cubic centimeters per day) which experienced a mortality of 34.1 per cent during this same 2 year period.

3 A decrease in the total hospital mortality during this 2 year period of 13.1 per cent over the average for the preceding 4 year period, or from 38.9 to 25.8 per cent.

4. In all deaths in patients treated by spinal drainage autopsies were carried out and in no instance did we observe any evidence of cerebellar herniation, medullary compression or "cone" formation. We attribute this to the slow removal of cerebrospinal fluid.

5 There was no increased hematoma formation in this group in which grossly bloody spinal fluid was 'drained dry' nor is there any evidence that spinal drainage in these patients tended to increase or prolong hemorrhage.

6 Of 5 patients receiving hypertonic sucrose review of the kidney sections revealed that a man aged 27 years, who received 1,340 cubic centimeters of 50 per cent sucrose showed no renal lesion, while a man aged 50 years, receiving 100 cubic centimeters of 50 per cent sucrose showed the most marked tubular change.

THE PATHOGENESIS AND TREATMENT OF UNILATERAL EXOPHTHALMOS

LOYAL DAVIS, M D, F A C S, and JOHN MARTIN, M D, Chicago, Illinois

A PATIENT who presents himself to a neurological surgeon because of unilateral exophthalmos, failing vision, and inco-ordination of the extra-ocular muscles has usually been examined by one or more physicians, including an ophthalmologist. Thus the ophthalmologist perhaps has the greatest opportunity to discover the many conditions which may produce unilateral exophthalmos, among the more common of which are intra-orbital inflammatory disease—either primary or secondary to an infected paranasal sinus, paralysis of the extra-ocular muscles, cavernous sinus thrombosis, congenital anatomical defects, angiomas or aneurysms, either within or behind the orbit, and tumors of various types, also either within or behind the orbit. Judging from the available reports of both neurological surgeons and ophthalmologists concerning the causative lesions in unilateral exophthalmos, one gains the impression that vascular lesions and tumors are found more frequently by far. This has been true in our experience. Many of the patients have been referred to us after ophthalmological study elsewhere. It is with a discussion of these types of lesions that this paper is primarily concerned.

In a series of 604 verified and 150 unverified intracranial tumors, we have seen 15 patients with unilateral exophthalmos. Of these, 9 of the patients were males and 6 were females. The youngest in the group was a boy of 15 years, the oldest patient was a man of 59. All of these patients were referred to us by other physicians after the simpler causes of their visual difficulties had been ruled out, and in each case the eventual treatment proposed was surgical. The operative findings divided them into 3 groups: (1) unilateral exophthalmos with tumors, (2) unilateral exophthalmos with aneurysms, and (3) tumor

or aneurysm suspects, the lesion being unidentified. Other patients with various types of exophthalmos have been seen, but they do not fall into this particular surgical category and are therefore not included in this discussion.

Among this group of patients there were 7 who had intracranial tumors. In each case the exophthalmos was strictly unilateral and in no instance was it of the pulsating form. The tumors in 4 cases were meningiomas: 2 being global meningiomas of the sphenoidal wing and 2 being meningiomas of the optic chiasm. One tumor still remains unclassified and the other was a glioma of the optic nerve.

The largest tumor of the group was a large spherical meningioma of the meningothelial cell type, larger than a tennis ball, which arose from the lateral portion of the right sphenoidal wing. At operation it was found that it did not extend past the midline to the left side. It lifted the frontal lobe up from its base and had also broken through the orbital roof. Growing forward behind the orbital roof it had produced almost complete immobility of the globe, and marked exophthalmos. Immediately after operation, after achieving removal of the tumor and of the roof of the orbit, the eye receded and on palpation and measurement there was a marked decrease in the tenseness and in the size of the eyeball. Verifying the position of the tumor of the skull, the bony orbital roof and lateral portion of the sphenoidal wing were found to be greatly thickened and bony (Fig. 1).

The other global tumor, smaller than the one just described, was situated on the pterional ridge and occurred just behind the Sylvian fissure. It was found that the tumor described in the first case was a dark, purple, meaty tumor, which was removed in its entirety with the aid of the surgical unit, but it was not removed.

and it was intimately attached to the underlying bone. The periorbital and alar areas, as well as the lateral wall of the orbit were rough, thick, and very vascular when the dura mater was stripped free. The lateral wall and roof of the orbit were removed back to the optic foramen and the bony attachment of the tumor was thoroughly sparked with a desiccating current. This tumor proved to be an angioblastic meningioma, and sections of portions of the removed bone showed a rich infiltration of the tumor into the bone. The exophthalmos continued to recede for several weeks following the operation (Fig. 2).

The 2 patients with meningioma *en plaque* had an exophthalmos of longer standing than did either of the two patients just described. In 1 of these patients the meningioma, being principally intra-orbital, presented itself at the enlarged optic foramen and extended sheet-like over the orbital contents just under the bony roof. Following removal of the tumor and a wide orbital decompression the patient's eye receded and his facial expression returned to normal. This tumor was the common variety of meningothelial cell type with many small whorls of cells but no psammoma bodies (2). Though its location certainly suggests that the tumor arose in the sheath of Schwann, slight impairment of visual acuity and moderate asymmetrical contraction of the visual field in that eye speak against it.

The other patient, a middle aged colored woman, had the most marked exophthalmos of any patient in the series. The eye was completely blind and motionless, and there was an edema of the conjunctiva and lids of many months standing. At operation a thick sheet of very vascular tumor tissue was found to extend over the floor of the anterior and middle cranial fossae on the left side, centering about the clinoid processes and alar ridge. It was impossible to remove all of the tumor and when an electric burr was used in an attempt to open the orbital roof dense vascular bone was removed to a depth of over one inch without even reaching the space of the orbit. The bone of the sphenoidal wing and the immediately adjacent cranial floor was everywhere rough, greatly thickened, and extremely bloody when it was rongueured or

stripped of either tumor tissue or dura mater. Following the operation there was a distinct improvement in the edema of the conjunctiva and eye lids, but the exophthalmos remained unchanged. This tumor likewise meningothelial in type, contained many vascular sinuses, large and small nests or whorls of cells, and many fine psammoma bodies (Fig. 3).

Another patient developed complete loss of vision marked proptosis, and paralysis of the extra-ocular muscles on the right, over a period of only 3 months. At operation he was found to have a highly vascular mass of tissue which occupied the chiasmal region, and extended laterally over the clinoid processes, the sphenoidal wing and the posterior half of the roof of the orbit. An extension of the tumor was also found in the greatly enlarged optic foramen. The patient withstood the operation very well, and a large portion of the tumor was removed, but on the third day he suddenly became comatose and expired within a few minutes. At autopsy many nodules from the size of small shot to that of a large grape were found over the basal dura mater particularly clustered about the foramina of exit of the cranial nerves. One could insert the tip of a finger into the optic foramen, and the orbital roof everywhere paper thin, was completely absent in one area 3 by 2 centimeters. There was no intra-orbital mass. Several pathologists have studied sections of both the main tumor mass and the scattered nodules. They all show the same tumor tissue, but to date it has not been classified. It is most likely however a carcinoma of some unusual type, possibly metastatic, though a complete autopsy did not reveal a primary lesion elsewhere in the body.

The remaining patient with a tumor was a boy of 15 who had an exophthalmos and complete blindness of the left eye. There were no other neurological findings, and the roentgenological studies of the orbits showed optic foramina of equal size. Nevertheless, it was suspected that he had a glioma of the optic nerve, and upon operation a large mass was found to obscure the left optic nerve and optic foramen completely. When the capsule was incised preparatory to its removal, soft granular tissue oozed from the opening. At

Fig 1 A large, solid meningioma arising from the right sphenoidal wing produced a homolateral non pulsating exophthalmos, shown here in the patient at the time of operation. There was a marked thickening of the bone of the sphenoidal wing and orbital roof. The tumor is of the meningothelial cell type, with but little reticulin formation, and with a tendency to form large whorl patterns.

that moment tremendous arterial hemorrhage occurred and only after a desperate struggle was it brought under control. Unfortunately, no tissue was obtained for histological verification. The boy's recovery was good and his exophthalmos has receded, probably because of the cranial decompression opening which was made at the time of operation.

Here, then, are 6 examples of unilateral exophthalmos with other variable neurological symptoms, occurring in the presence of a variety of tumors in or immediately behind the orbit. As will be pointed out later, the tumor type, its exact location, its duration, and its effect on the bones of the cranial fossae are matters of importance in an understanding of the mechanism of the exophthalmos.

Included in this series are 4 patients with aneurysms. One patient, a woman of 48

years, presented an exophthalmos together with other cranial nerve symptoms which led to a diagnosis of a right sided paratrigeminal lesion. Blood was found in her cerebrospinal fluid, and it was believed that her symptoms were due to a bleeding aneurysm of the intracranial portion of the internal carotid artery. Her protruding eye did not pulsate, and an intracranial bruit was not definitely verified. She left the hospital without treatment and has since died elsewhere without an autopsy having been performed.

Another patient, a woman of 41 years, developed a pulsating unilateral exophthalmos of the right eye over a period of several years, with no preceding history of trauma to the head. The eye protruded markedly, so that it was estimated that 50 per cent of the sclera was exposed. The lids were purple, edematous, and thickened with a tangled subcutaneous

Fig. 2. The thickening of the alar and pterional bone, as well as that of the posterior orbital area, locates the site of the globular meningioma of angiotlastic type which infiltrated the underlying vascular hyperplastic bone. The vascular sinuses of the tumor are lined by flattened and endothelial cells. Inside the solid portions are composed of large polyhedral meningiomatous cells. The photograph of the patient shows her condition on discharge after operation, here there is already marked recession of the exophthalmos.

mass of tortuous small veins. The scleral vessels were large and pulsating. There was only a slight limitation of the motion of the eyeball, however, and there was no diplopia. Visual acuity of the affected eye was 20/40 of the left eye 20/50. The supra-orbital angular, nasal and facial veins were visible without palpation and were as large as a common lead pencil. There was a thrill and bruit through

out the skull and right side of the face. The eye actually bounded with the pulse. It was impossible to obliterate completely the pulsations and bruit by digital pressure in the neck, though the patient stated that when such pressure was applied she herself could no longer hear the bruit. At operation the right external carotid and right common carotid arteries were ligated after it was found that

Fig 3 This meningioma *en plaque* of long standing caused a tremendous thickening of the sphenoidal wing as well as of the orbital roof and the floor of the middle cranial fossa. It is a meningotheelial meningioma of low reticulin content, containing psammoma bodies and showing well defined small whorl patterns. The patient is shown just before operation, when edema of the lids was so severe as to cover in most part the markedly exophthalmic left eye.

their temporary occlusion produced no signs of cerebral embarrassment. The jugular vein was unusually large but the carotid artery was of normal size. No communication between the two in the neck was seen. Following the ligation there was a complete and immediate cessation of the bruit, pulsations were gone in the cheek, in the angle between the eye and nose and over the forehead and the eye not only ceased to pulsate but it receded remarkably into the orbit. The scleral and palpebral vessels were greatly diminished in size and, in

fact the patient's facial expression was changed in great measure. It is possible, however, that due to the many possibilities of arterial and venous communication in this patient the internal carotid may eventually require ligation to give a permanent result (Fig 4).

Two other patients, both men about 38 years old and both with a protruding pulsating left eye had a history of trauma to the head immediately preceding the onset of their exophthalmos. The one patient developed a

Fig. 4. An arteriovenous aneurysm caused the right eye in this patient to bound with the pulse and to protrude markedly from the orbit. The huge supra-orbital, angular and facial veins, the smaller tangled masses of veins on the upper lid, and the dusky purplish sclera with its dilated vessels, all added to the grotesque appearance of the face. Though the exact point of arteriovenous communication was not determined, ligation of the right common carotid and right external carotid arteries caused great decrease in the proptosis and prominence of the veins, as well as cessation of the loud bruit. The upper two photographs were taken before operation; the lower two show the improvement after ligation of the carotids.

prominence and pulsation of the left eye 4 months after having been struck in the left occipital region by a brick. He became conscious of a pounding whirling head noise, increased on exertion 6 months after the injury, and he developed a diplopia on looking to the left, in 7 months. His left eye was very prominent, it pulsated synchronously with the pulse, and the scleral and palpebral vessels were engorged and tortuous. Following ligation

of the common carotid artery the pulsations ceased, the eye receded, and the engorgement of the scleral and palpebral vessels disappeared without the development of any neurological complications (Fig. 5).

The second patient was pinned between the floor of a garage and a motor which fell from its frame while he was working beneath an automobile. In addition to his left-sided pulsating exophthalmos, which developed 1

Fig 5 Struck in the left occipital region by a brick, this man, 4 months later, developed a left sided pulsating exophthalmos, dilatation of the scleral vessels, and a loud bruit. The upper pictures show his condition before operation, and the lower photographs show his eyes postoperatively when, after ligation of the left common carotid artery, his exophthalmos receded, the scleral vessels returned to normal, and the bruit disappeared

month following the injury, this man had a paralysis of various cranial nerves, including a bilateral facial paralysis. He complained of constant head pains and head noises. It was believed that he, like the preceding patient, had an arteriovenous aneurysm of the internal carotid artery and cavernous sinus. The left common carotid artery was ligated first, and a few days later the left external carotid was likewise tied off. One week following ligation of the external carotid the patient suddenly lost his speech and the power to move his right arm. He recovered in 2 or 3 minutes, and after a period of 5 minutes again lost his speech, which defect has remained permanently. Upon discharge his exophthalmos had improved greatly, and peri-orbital and scleral engorgement had disappeared, and he no longer complained of head noises, (Fig 6)

Three other patients were seen, all of whom had a unilateral, nonpulsating exophthalmos without other significant neurological symptoms. After careful neurological and roentgenological examination they were believed to have retro-orbital or intra-orbital tumors and were, accordingly, operated upon. No tumor was found at any place in the anterior or mid-

dle cranial fossa nor toward the midline about the chiasm and sella and in these patients the bone of the roof of the orbit and the sphenoidal wing was only moderately thickened. In each case the roof of the orbit was removed, and in each case the orbital contents rose into the decompression opening due to an apparent increase of intra-orbital tension. No tumor within the orbit was found in any of these 3 patients. In each patient decompression of the orbit relieved the exophthalmos and restored the facial expression to a normal state.

The 2 remaining patients, both with a left sided, non-pulsating exophthalmos with scleral and palpebral venous engorgement and pupillary fixation in dilatation, were believed to have tumors in the orbit or intracranially behind the orbit, but both refused operation and they have not been seen in follow-up examinations.

ANALYSIS

Six patients have been shown at operation to have tumors in or behind the orbit, with a co-existing, non-pulsating, homolateral exophthalmos. All 6 showed definite x-ray evidence of a tumor, in the thickening of the sphenoidal

Fig. 4. An arterio-venous aneurysm caused the right eye in this patient to bomb with the pulse and to protrude markedly from the orbit. The huge supra orbital, angular and facial veins, the smaller tangled masses of veins on the upper lid, and the dusky purplish sclera with its dilated vessels, all added to the grotesque appearance of the face. Though the exact point of arterio-venous communication was not determined, ligation of the right common carotid and right external carotid arteries caused great decrease in the protuberance of the veins, as well as cessation of the load break. The upper two photographs were taken before operation; the lower two show the improvement after ligation of the carotids.

prominence and pulsation of the left eye 4 months after having been struck in the left occipital region by a brick. He became conscious of a pounding whurring head noise increased on exertion 6 months after the injury, and he developed a diplopia on looking to the left, in 7 months. His left eye was very prominent; it pulsed synchronously with the pulse and the scleral and palpebral vessels were engorged and tortuous. Following liga-

tion of the common carotid artery, the pulsations ceased, the eye receded, and the engorgement of the scleral and palpebral vessels disappeared without the development of any neurological complications (Fig. 5).

The second patient was pinned between the floor of a garage and a motor which fell from its frame while he was working beneath an automobile. In addition to his left sided pulsating exophthalmos, which developed 1

upon exertion X-ray evidence of the aneurysms was lacking in every case, though we have seen positive evidence of bone erosion and deposits of calcium in other patients with aneurysms of the internal carotid. In 3 of our 4 cases the exophthalmos was pulsating, and in all the patients the prominence of the palpebral veins, the dilatation of the scleral vessels, and the increased lacrimation were much more marked than they were in the patients with tumors. Moreover, the exophthalmic eye was a much more startling object to behold. Certain other patients who have been seen with aneurysms, but without exophthalmos, have had a papilledema as well as a bruit, both of which improved following various combinations of carotid artery ligation.

In investigating the reports of others in their experience with unilateral exophthalmos, one is confronted by a variety of opinions as to the causes of, and the mechanics important in, such a condition. Randolph believed that sarcoma was by far the most common form of intra-orbital tumor, and he cited it as a prominent cause of unilateral exophthalmos, but he did not analyze any cases of retro-orbital tumors. In a series of 807 intracranial tumors reported by Elsberg, Hare, and Dyke, 15 patients had unilateral exophthalmos. Of these 15, 10 patients had meningiomas. There were 2 osteomas, 1 adenoma, 1 epidermoid, and 1 "Paget's disease with tumor." These men did not believe that venous stasis, which could be supposed to result from local or generalized increase of pressure, is a cause of exophthalmos. They never saw such a condition in any of their patients, and neither have we. Such a mechanism has not been satisfactorily demonstrated in animals in which attempts have been made experimentally to produce exophthalmos. In accord with our own observations, they noted that in most of their patients limitation of the eyeball was in all directions as a rule, but the degree of impaired motion was not necessarily in direct proportion to the degree of protrusion. They believed that the exophthalmos was most often due to a perforation of the tumor into the orbit, thickening of the orbital walls, extension of the tumor from the cranial cavity through the orbital fissures or optic foramen,

or a transference through these openings of the increased intracranial pressure. Our experience with 6 patients completely substantiates this explanation for the mechanisms of production of unilateral exophthalmos in patients of this category.

The degree of exophthalmos in the presence of a meningioma depends upon the degree of encroachment upon the orbital space by the hyperostosis of the bony walls of the orbit, and upon the bulk of tumor tissue which has grown into the orbit either by means of erosion or through the natural foramina of the orbit. We can accept, without specific data to support such a contention, the theory that the venous return flow of blood must be embarrassed to a certain degree under such conditions, and that there may well be an increase in the fibrous content of the fatty tissues surrounding the globe and muscles. We do not believe that Mueller's muscle is a factor in the production of unilateral exophthalmos in the human subject. Optic nerve gliomas characteristically produce an enlargement of the optic foramen through which they may grow forward, but not all optic gliomas produce an exophthalmos. Though apparently it is not commonly true, yet it is possible that a tumor, neither meningioma nor optic glioma, may produce unilateral exophthalmos when it lies behind the orbit. Our 1 unclassified tumor in this group caused no bony change other than erosion of the roof of the orbit and optic foramen, through which openings it grew into the orbit, pushing the orbital contents before it. The closer to the orbit the site of primary tumor growth, the earlier will be the appearance of the exophthalmos, and accordingly, the tumor of long standing will have caused a greater degree of exophthalmos than the tumor of recent growth.

Sugar and Meyer, commenting upon the exophthalmos in the presence of aneurysms, state "Of the several anatomic causes of pulsating exophthalmos the most frequent is traumatic rupture of the internal carotid artery in its passage through the cavernous sinus." They point out that aneurysms may be traumatic, luetic, arteriosclerotic, or congenital. They explain the mechanism of the exophthalmos as follows:

After rupture of the internal carotid artery, there is an overflow of arterial blood into the venous sinus with consequent increase in the venous pressure and reversal of venous flow in the ophthalmic veins and their tributaries. The resulting stasis, edema, and increase in blood volume in the venous bed produce exophthalmos. Through the dilated venous channels the arterial pulsation is transmitted to the eyeball and orbital tissues. Since the ophthalmic veins are the only tributaries of the cavernous sinus which have no dense tissues around them, such as is present around the intracranial venous sinuses, they may dilate and give rise to the pulsating large venous masses often seen at the internal angle of the eye, usually consisting of the superior ophthalmic vein formed by the union of the supra-orbital and angular veins."

Cushing and Bailey do not report any case of pulsating exophthalmos in the presence of an angioma arteriale, nor have any patients with an arterial or venous angioma of the cerebrum or cerebellum in our series been observed to have a pulsating unilateral exophthalmos. They do point out, however, that though no pulsation is seen in the eye in such patients, frequently a bruit can be heard when the globe is auscultated when an angioma arteriale is present in the brain, and that therefore a unilateral exophthalmos with audible bruit in the globe need not necessarily be an infallible sign of arteriovenous fistula between the carotid and cavernous sinus. Such a matter of differential diagnosis is important, for the treatment of arteriovenous aneurysms and of arterial or venous angiomata is quite different.

Smelser produced exophthalmos in thyroidectomized guinea pigs by the injection of pituitary extract but unilateral or bilateral extirpation of the cervical sympathetic ganglia did not affect the exophthalmos. These animals had been prepared previously by the removal of Mueller's muscle (a large muscle in the guinea pig) and the exophthalmos persisted even after death. Therefore such exophthalmos could not be due to continuous sympathetic stimulation or the direct result of continued contraction of Mueller's muscle. He did find however a hypertrophy of the

periglobal soft tissues. It would be difficult to explain the exophthalmos seen in our patients on the basis of overactivity of the sympathetic, and the muscle of Mueller is too small a structure in man to tilt the eye outward, and it seems improbable that it could cause such marked venous stasis by its contraction. That a fibrous tissue hypertrophy would result, Skjeldgaard agrees that the exophthalmos present in patients with intracranial tumors is not due to sympathetic stimulation.

Many a neurological surgeon has had the opportunity to observe patients with intracranial tumors and aneurysms who did not have an exophthalmos. Large retro-orbital tumors, such as those large old chromophobe adenomas of long standing that may reach laterally and anteriorly far beyond the stippled confines of the sella turcica or the large tumors of the under surface of the temporal lobe which push forward toward the orbit, are of common occurrence, but they do not cause unilateral exophthalmos. A terrific increase in intracranial pressure such as follows the rapid growth of certain tumors of the posterior cranial fossa, does not produce unilateral exophthalmos. Other possible causes for the exophthalmos having been eliminated, one must always suspect a retro-orbital tumor either confined within the intracranial cavity or actually growing into the orbital space or an arteriovenous aneurysm. If the lesion be a tumor there will usually be confirmatory roentgenological evidence. If it be an aneurysm, there may or may not be roentgenological findings, there will usually be a bruit on the involved side, there may be a history of trauma and there is a striking engorgement of the palpebral and scleral vessels. The exophthalmos will more than likely pulsate when an aneurysm is present, whereas it will be non-pulsating when caused by a tumor.

The treatment of unilateral exophthalmos, whether due to tumor or aneurysm, is surgical. The tumor must be removed as completely as possible, both its intracranial and intracranial portions, and all bone which has been invaded must be removed, where this is feasible to prevent a recurrence. The bone removal is especially important where a failed

THE TREATMENT OF DIFFUSE PERITONITIS BY THE DIRECT INTRAPERITONEAL INTRODUCTION OF SULFANILAMIDE

S. ROSENBERG M.D., F.A.C.S. and NORMAN M. WALL, M.D. Pittsburgh, Pennsylvania

EVER since the more recent work on the therapeutic activity and mode of action of sulfanilamide there have been various reports on the effects and methods by which sulfanilamide achieves its results, for the most part, on beta hemolytic streptococci. All authors have stressed the fact that there is no bactericidal effect in the sense that an antiseptic like iodine might attack infective organisms. This we feel has given rise to the general impression that in order to be effective in a specified local area, sulfanilamide must be given systemically. It is our impression not yet definitely proved, that when sulfanilamide can be utilized locally—such as in the peritoneal cavity—and the concentration maintained at the proper level the same therapeutic result and even a better result may be obtained than by its pure systemic use.

Long and Bliss (7) in one of their original articles showed that sulfanilamide in certain concentrations when placed in contact with cultures containing beta hemolytic streptococcus definitely inhibited multiplication of the organisms.

Colebrook and Kenny (2) have pointed out that the serum of a patient ill with streptococic puerperal sepsis becomes increasingly bacteriostatic to the organism after multiple doses of prontosil. Long and Bliss were unable to verify this work, partly due to the fact that human serum is often bactericidal to strains of streptococci. It is probable that statements such as that of Colebrook and Kenny have been to a great extent responsible for the lack of utilization of sulfanilamide as a local agent in the treatment of various infections.

From the Surgical Service of Herbert Frankenstein, M.D., and Isaac Kaufmann Foundation of the Montefiore Hospital, Pittsburgh, Pennsylvania.

Domagk, in his original paper made note of the importance of phagocytosis in the action of sulfanilamide. Levaditi and Valsman attributed this increase in phagocytosis to the interference with the bacterial capsule formation.

Long and Bliss (8) conclude that there is no bactericidal effect in the action of sulfanilamide and moreover definitely decide that the serums of patients treated with sulfanilamide exert little if any bactericidal effect on beta hemolytic streptococci. They feel that there is a definite bacteriostatic effect *in vivo* as well as *in vitro* and ascribe to phagocytosis the so called clean-up rôle.

The fundamental observations of Marshall show that sulfanilamide is quickly absorbed when it is administered orally or parenterally. He has shown that it becomes distributed with surprising uniformity throughout all the tissues, including the tissues of the infected site.

Colebrook, Battle, and O'Meara (1) have definitely shown that it made no essential difference whether the sulfanilamide-laden blood was obtained from a treated patient or through the addition of the chemical to normal blood. They both had the property to kill beta hemolytic streptococci and prevent their multiplication *in vitro*.

J. S. Lockwood (5) has beautifully demonstrated that phagocytosis is not necessary (*in vitro* at least) to interfere with bacterial growth. Interference takes place to the same extent in human serum which contains no phagocytes. Moreover he has also shown that the presence of peptone is important in the action of sulfanilamide. He thus concluded that sulfanilamide acts upon hemolytic streptococci by interference with their protein digesting mechanism. This accounts for the fact that sulfanilamide is of greatest

value in lesions in which there is a minimum of tissue destruction

In a later rather extensive and detailed report Lockwood (6) comes to the following conclusion "It is possible that sulfanilamide combines in some way with the free amino-nitrogen of protein degradation products and renders them unsuitable for bacterial utilization", thus allowing the bacteria to die literally by starvation. This concept would appear to explain why the sulfanilamide compounds are active only against certain organisms. It begins to appear that sulfanilamide is not so much specific against any organism *per se* as it is particularly beneficial against any organism which is not protected by a strong wall composed of proteolytic products. Thus it is known that sulfanilamide is not effective against hemolytic streptococci in abscesses, but may be effective against staphylococcus in the presence of a staphylococcic cellulitis. This preliminary survey brings us to our main thesis: *i.e. the local application of sulfanilamide to the healing of infected tissues*. We have tried to bring out the fact that the main idea of sulfanilamide therapy is to secure an effective concentration of sulfanilamide or possibly a direct derivative at the infected site. We reason then, that sulfanilamide should be utilized locally in high concentration whenever practical. We cannot understand why this particular phase of sulfanilamide therapy should have been pushed into the background. If unmodified sulfanilamide is the effective agent, one should logically be able to utilize it in this manner and if an oxidation product is the active agent, there is no reason why this cannot be formed in a wound such as a granulating cavity or inflamed peritoneal surface. If Lockwood's experiments have good foundation, and we have every reason to believe that they have, then the most important aim in parenteral therapy is to get a high concentration of sulfanilamide at the infected site. Surely this can often be obtained more easily by local introduction than by the systemic route.

It occurred to us that the peritoneum would be an ideal site to test this theory. If, on encountering a diffuse or localized peritonitis at operation, one could instill sulfanilamide in the form of a crystalline product before closing

Graph 1 Experiment 1

the peritoneal cavity, one might then have a definite protection against the further spread of the process, provided the focus were removed. In no way do we wish to deprecate the valuable effect of sulfanilamide given subcutaneously in the treatment of peritonitis, for we know it to be of inestimable importance. However, it is our feeling that sulfanilamide, when introduced into the peritoneal cavity in the form of a crystalline powder and subsequently reinforced by subcutaneous introduction of a 0.8 per cent solution of sulfanilamide, is a definite advance in our armamentarium against the ravages of peritonitis. We know certainly that the sulfanilamide introduced into the inflamed peritoneal cavity of humans, permeates the tissues rapidly and is found in the blood stream soon afterward in a fairly high concentration. It is in all probability re-excreted into the peritoneal cavity as well as other tissues. Inasmuch as the number of cases of generalized peritonitis any one man can have is limited we felt that if we could reproduce in rats the conditions found in human peritonitis, we might have some justification for our clinical impression, and thus perhaps encourage others to utilize sulfanilamide in this way.

In our experiments we have made our problem rather difficult by selecting no particular

I P intraperitoneal

organism Cultures were taken from the aspirated contents of acute suppurative appendices or from the peritoneum of peritonitis cases. We felt that the human peritoneum has no chance to select the particular organism which invades it and in this sense we might reproduce the situation in the rat. Thus, varying amounts of different cultures were injected intraperitoneally into two rats, one of which was given a simultaneous intraperitoneal injection of sulfanilamide suspended in saline. The control rat was given a corresponding amount of saline intraperitoneally to equalize any factor of dilution. The results are tabulated in Table I.

In this series of 42 white rats injected subcutaneously with varying amounts of cultures consisting for the most part of *Bacillus coli*, *Streptococcus nonhemolyticus*, and gram positive diplococci, 20 of a possible 21 unprotected rats died in various stages of peritonitis. In contrast to this 11 of 21 rats protected by intraperitoneal sulfanilamide lived indefinitely. One rat died in convulsions, apparently from an overdose of sulfanilamide and 1 died 36

hours after the unprotected rat. We emphasize that the conditions of the experiment were rather severe inasmuch as a variety of organisms were introduced and the streptococcus was at no time of the beta hemolytic type. Perhaps if only one organism were used the results would have been even more striking. The results are expressed in Graph 1.

In the second phase of the study an even more rugged type of experiment was set up. An attempt was made more faithfully to reproduce the situation met with in human peritonitis. In other words sulfanilamide was not introduced for varying lengths of time following the intraperitoneal injection of mixed cultures and consequently a peritonitis of varying duration was present when sulfanilamide was introduced. Another variation was introduced in that, in addition to instilling the drug intraperitoneally another rat was utilized for the subcutaneous administration of a similar dose. Thus an attempt was made to show that the intraperitoneal route has advantages or disadvantages over the subcutaneous route in the administration of sulfanilamide. It

S. Q. subcutaneous

should be stressed that a peritonitis of 4 to 20 hours' duration in a rat of 150 to 200 grams is comparable in severity to one of days in a human being. It also should be emphasized that many of these rats were already extremely ill when the sulfanilamide was introduced. Occasionally an untoward result occurred, such as an unprotected rat living while the rat with sulfanilamide died. We cannot always explain such results. The variation in individual rats and susceptibility to dosage of sulfanilamide probably are factors. These results are tabulated in Table II.

In this experiment the ability to save the treated rats was not as great as we would have liked. However, of a possible 24 rats protected with intraperitoneal sulfanilamide, there were 17 good results (10 of the rats lived indefinitely). More detailed treatment would probably have been even more productive of good results. The subcutaneous route showed some degree of curative value also, but not to the same extent as the intraperitoneal route. In this phase of the experiment, of 24 rats protected with subcutaneous sulfanilamide there were 7 good results (5 of which lived indefinitely). In the control rats, of 22, 1 rat lived. These results are shown in Graph 2. It should be re-emphasized that this was a rather rigorous experiment, peritonitis had already set in for a varying number of hours and the animals were already quite sick when they were treated.

In summarizing experiment 2 the general effectiveness of sulfanilamide can be shown (Graph 3). Thus of 48 rats given sulfanila-

midate either intraperitoneally or subcutaneously from 4 to 20 hours after peritonitis had set in there were 24 good results.

The final estimate of this therapeutic measure rests with its trial in human patients who have fallen victim to diffuse peritonitis. We must reiterate that our experience has been very small. There have been in all only 4 cases of widely different variety in which it has been utilized. None of these cases necessarily proves anything with the exception of the fact that sulfanilamide which is introduced intraperitoneally is in no way locally destructive or harmful to delicate tissue such as the serosa of bowel.

SUMMARY AND CONCLUSION

Most of the papers which have been written to date have emphasized the use of sulfanilamide in a systemic manner. The main purpose of this work is to show that sulfanilamide acts locally even though indirectly in some fashion which is not yet clear. If sulfanilamide can be applied to a local area and kept in contact with this area, it is taken up by the tissues and permeates them thoroughly. This is evidenced by its detection in the blood in very appreciable quantities following intraperitoneal implantation in humans. Traces can even be detected in the blood stream following local application to a granulating wound such as a varicose ulcer. We have demonstrated this fact in human beings to our complete satisfaction.

We feel that the peritoneum is an ideal site for the local use of sulfanilamide. At opera-

admit defeat Sulfanilamide given intraperitoneally and subcutaneously in adequate dosage gives the surgeon a positive weapon with which to fight this insidious infection and with which to meet it on perhaps slightly more equal terms

CASE 1 M P, aged 8½ years, female, was admitted to the hospital February 24, 1940, operation was done February 24, 1940, and she was discharged April 1, 1940 Patient gave a history of abdominal pain which had been present 3 days

Physical examination showed a very sick child with abdomen generally distended, rigid, and tender Peristalsis was absent Temperature was 103.6 degrees, pulse, 160, respirations, 35 The white blood cells numbered 50,153, polymorphonuclears, 93 per cent, lymphocytes, 3 per cent, large mononuclears, 4 per cent

At operation there was found a diffuse purulent peritonitis The appendix, perforated and pointing up under the liver, was removed, Penrose drains were inserted, and 15 grains of sulfanilamide was placed in the peritoneal cavity before closure Culture from the peritoneal cavity showed the *Bacillus coli* and the streptococcus

Convalescence was stormy and patient was given 4 grams of sulfanilamide daily in 24 hour periods for 7 days

Following this she was given sulfanilamide by mouth 1-1.10 grains three times a day for 2 days On discharge the wound was healed and there was no evidence of residual abscesses

CASE 2 M R, aged 45 years, female, was admitted to the hospital, April 24, 1940, operation was done April 26, 1940 In hospital at present May 24, 1940

In the past 10 years patient had 5 laparotomies for pelvic disease The last one, one year before admission, was performed to relieve intestinal obstruction Patient had partial intestinal obstruction when admitted After Wangenstein drainage and intravenous glucose, laparotomy was performed The bowel was so thinned out and adhesions so firm that the bowel was opened in 3 places There was gross contamination The obstruction was relieved and an ileostomy was performed Sixty grains of sulfanilamide were placed in the peritoneal cavity before closure Peritoneal culture showed *Bacillus coli*, streptococcus, Gram positive diplococci, Gram positive bacilli Blood sulfanilamide taken the following day showed 5.7 milligrams per 100 cubic centimeters She was subsequently given sulfanilamide subcutaneously in addition

There was little temperature rise and convalescence has been remarkably smooth, except for the ileostomy opening which has not yet closed

CASE 3 Dr M M, aged 26 years, male, was admitted to the hospital May 20, 1940, operation was performed May 20, 1940, and he is at present convalescing

Patient had an appendiceal abscess drained 3 months previously and a persistent fistula remained Several hours before admission patient had abdominal pain with emesis, rise in temperature to 102 degrees, pulse 140 A diagnosis of intestinal obstruction was made The white blood cells numbered 18,200, polymorphonuclears, 84 per cent, lymphocytes, 15 per cent, and mononuclears, 1 per cent Sedimentation time was 19 minutes

At operation the free peritoneal cavity was entered into, the obstruction was relieved, and a pus pocket encountered Gross contamination was present The terminal ileum was suggestive of regional enteritis The appendix appeared to be involved in an acute process and was removed The fistulous tract was cut across Forty-five grains of sulfanilamide was introduced before the wound was closed The abdomen was closed with drainage

Culture from the peritoneal cavity showed *Bacillus coli*, streptococci, and Gram positive diplococci

Convalescence was uneventful and on the third day after operation, the temperature reached normal Forty-eight hours after operation the blood sulfanilamide determination showed a trace present

CASE 4 W A, aged 43 years, was admitted to the hospital, March 13, 1940, operation was performed March 13, 1940, and patient was discharged March 26, 1940 Diagnosis acute gangrenous appendicitis Patient gave a history of 36 hours of generalized abdominal pain localizing in the right lower quadrant, for which castor oil, epsom salts, and ex-lax were taken Vomiting occurred twice

Physical examination revealed generalized abdominal tenderness, rebound tenderness and rigidity, moderate distention peristalsis, absent The temperature was 100.8 degrees, pulse, 100, respirations, 20 Urine was negative on analysis The white blood cells numbered 16,300, polymorphonuclears, 94 per cent, lymphocytes, 6 per cent

At operation the peritoneal cavity was found to be filled with milky fluid, which had some odor No gross perforation was noted, but the appendix was gangrenous and was covered with exudate The bowels were diffusely reddened Culture was taken

The appendix was removed and 15 grains of powdered sulfanilamide was inserted into the peritoneal cavity at the site of appendectomy One Penrose drain was utilized The peritoneal swab was allowed to dry and was not planted until the next day The final report was no growth Blood sulfanilamide was, 24 hours after, 1 milligram per 100 cubic centimeters, 48 hours after, faint trace

The patient had an uneventful convalescence and was discharged on the thirteenth day

We feel that this patient had peritoneal contamination but the swab was permitted to dry before planting and thus the laboratory proof is lacking

Thanks are extended to Dr H Frankenstein for the use of his cases, to Dr K Yardumian, pathologist, for his intimate advice and co-operation, and to Miss Rhea Klein for her bacteriological studies

Graph 2. Experiment 2.

Graph 3. Summary of Experiment 2.

tion, if one encounters a diffuse peritonitis, sulfanilamide powder in the dosage of 1 to 4 grams can be placed in the peritoneal cavity after removal of the focus and before closure is carried out.

Our experiments with rats although by no means conclusive show some degree of protection afforded by intraperitoneal implantation of sulfanilamide. The first experiment in no way settles the contention that the beneficial effect of sulfanilamide was due to its local effect although we lean to this explanation. However more experiments are being conducted to prove this point. The second experiment tends to confirm in a small way that intraperitoneal sulfanilamide has some advantage over the parenteral method suggesting that the action is more than that of absorption and systemic action, and probably due to sulfanilamide action because of increase in the drug concentration at this point. We are sure of one fact, and that is that intraperitoneal sulfanilamide is not irritating to the peritoneum and apparently is not harmful to the individual. We feel it is advantageous to be able to obtain a high concentration of sulfanilamide

in the peritoneal cavity at the time of and immediately following operation. We must emphasize that in the human being one cannot depend on the one instillation of intraperitoneal sulfanilamide. This must be immediately augmented by subcutaneous sulfanilamide. Ravdin has shown a remarkably low mortality rate in the treatment of all types of acute appendicitis since the subcutaneous use of sulfanilamide has been introduced. We feel that this is a definite forward step in the treatment of peritonitis. It is our opinion that the introduction of powdered sulfanilamide into the peritoneal cavity at operation after the removal of the offending focus will result in an even lower mortality rate. This procedure is not offered as any substitute for time honored and well established methods which are utilized in the treatment of peritonitis, but merely as an additional weapon in the constant struggle against this dread disease.

Many times we have stood by the bedside feeling terribly helpless in the presence of a slowly advancing diffuse peritonitis, hoping against hope that nature's defenses would be able to stem this awful invader. Too many times the invader has won and we have had to

Since submitting this paper we have had 6 cases of generalized peritonitis secondary to perforated appendices in which intraperitoneal sulfanilamide was used. All of these cases have recovered.

THE TREATMENT OF ACUTE APPENDICITIS IN A MUNICIPAL HOSPITAL

JOHN BURKE, M.D. and HORACE F. KUHN, M.D. Buffalo, New York

AS a rule, the patient undergoing treatment in the average municipal hospital is in a more advanced stage of disease at the time of his hospital admission, and, as he is from the so called "under-privileged" group is usually in less satisfactory physical condition at the onset of his disease. For these reasons, we felt it worth-while to report the results of the treatment of acute appendicitis in the period 1935-1940 at the Edward J. Meyer Memorial Hospital. This hospital is operated by the City of Buffalo and is a general hospital of 1 063 beds. The patients, in the vast majority receive some form of city or county aid. Patients paying their own hospital bills constitute not more than 5 per cent of the patient total. Therapy was carried out by the attending or by the resident staff under the direct supervision of the attending staff so that the study represents the work of a fairly large group of surgeons. The basic therapy and operative technique however did not vary significantly during the period of this study. Radical therapy was carried out except in a few instances in which the condition of the patient did not permit it. Frank appendiceal abscesses were also treated conservatively until an optimum time for operation was reached. During this period 527 patients

with acute appendicitis have been treated. In this study no case was accepted as one of acute appendicitis without confirmation by the pathologist, except those cases of appendiceal abscess in which the appendix was not removed.

ACUTE NONPERFORATED APPENDICITIS

Three hundred and forty cases of acute nonperforated appendicitis were treated during this period, with 2 deaths, or a mortality rate of 0.58 per cent. Both of these deaths occurred during the first year of this study. One of these patients suffered a pulmonary embolism on his seventh postoperative day his second day out of bed. The other a child was suffering from measles at the time of the appendicitis attack, and died on the fourth postoperative day with a clinical diagnosis of generalized peritonitis.

In this group surgery was carried out immediately following admission and diagnosis, except in a few instances wherein replenishment of fluid loss was considered advisable. The operation was performed in all cases within 12 hours of hospital admission. With rare exceptions the McBurney incision was used with or without the Weir extension. Gas and ether anesthesia was used in 318 cases, spinal anesthesia in 18 and local anesthesia in 4 cases. Both deaths occurred in the first group. Morphine was given after operation as needed. Fluid requirements were met by oral ad

In the cases compiled from the literature (1) a total of 4,344 were perforated, or 20.96 per cent of the acute cases. In our series 187 cases were perforated, or 35.4 per cent of the total. This would seem to indicate that appendicitis is seen in graver form in the municipal hospital. The usual causes of procrastination and purgation are, as usual, responsible.

Perforation with localized peritonitis occurred in 44 cases. Of these 39 recovered and 5 died, a mortality of 11.3 per cent. The causes of death were (1) generalized peritonitis in 4 cases—autopsy, (2) localized peritonitis with massive intra abdominal hemorrhage 1 case—confirmed at autopsy. Drainage was used in 24 cases, with 3 deaths, a mortality of 12.5 per cent. No drainage was used in 16 cases 1 death occurred or a 6.3 per cent mortality.

In these cases it is more difficult to assay the rôle of drainage as it was usually employed in the presence of small collections of pus or necrotic material.

In résumé as to perforation with peritonitis, there was a total of 127 cases with 18 deaths or a 14.1 per cent mortality.

PERFORATION WITH ABSCESS FORMATION

Our treatment of perforation with abscess formation (the presence of a mass at the time of admission) has been definitely conservative. Patients were not operated upon until their general condition was satisfactory and it was evident that the abscess wall was sufficiently firm to permit its incision without risk of further peritoneal contamination. Limitation of fluids by mouth and parenteral fluid administration together with adequate doses of morphine were employed according to the condition of the patient. Here again, blood transfusions have been used with increasing frequency. Drainage has been carried out as an extraperitoneal procedure either through the abdominal wall, rectum, or vagina, as the occasion has indicated. The detailed treatment of the appendiceal and postappendiceal abscess will be discussed in a later paper. The appendix is removed at the time of drainage only when it is easily accessible and when its removal can be carried out without fear of breaking down the abscess wall. All patients whose appendices had not been removed were informed of this and requested to return in 8 to 12 weeks for appendectomy.

Abscess was present in 57 cases. Of these 7 died, a mortality of 12 per cent.

The causes of death were (1) Generalized peritonitis—2 cases (no autopsies—appendectomy performed in both instances) (2)

postoperative shock—2 cases (1 boy, aged 4, did not recover from the anesthesia and died 4 hours after operation. The other patient died within the first 24 hours) (3) wound disruption with secondary hemorrhage 7th postoperative day (no autopsy) (4) acute cardiac dilatation induced by insulin shock, sixteenth postoperative day (no autopsy) (5) pulmonary embolism, eleventh day (no autopsy).

As our mortality rate for the treatment of abscess is somewhat higher than the average of the reported series, we are inclined to think that errors in judgment or technique are the responsible factors. Omission of appendectomy might have eliminated the 2 deaths from generalized peritonitis. The 2 "shock" cases may be blamed on poor judgment or technique. If these 4 fatalities had been prevented, the mortality rate would have been quite respectable.

NON-OPERATIVE THERAPY

Nine patients with acute appendicitis, presumably with peritonitis, were treated without operation because they were *in extremis* at the time of admission, and at no time were possible operative risks. All of these patients died, but because only 3 had postmortem examinations these 3 alone were considered as proved cases of appendicitis.

SUMMARY

In a 5 year period 1935-1940, 527 patients with acute appendicitis were treated at the Edward J. Meyer Memorial Hospital. These cases have been subdivided as acute non-perforated, acute perforated with generalized or localized peritonitis, acute perforated with abscess. The results compared with those found in the recent literature are shown briefly in Table I.

nective tissue These nuclei are shorter and broader than normal and arise in the adventitia True inflammatory phenomena, such as emigrations of leucocytes are entirely absent

Nichols (19), in March, 1899, reported a case in which he observed thickening of the skin, absence of fatty tissue and adherence of the dense, fibrous bands to the skin Elsewhere the epidermis, dermis, and subcutaneous tissue were normal He noted an increased proliferation of connective tissue cells in and about the blood vessels, some fasciculi of the fascial bands were composed mainly of cells The sweat glands were numerous and unchanged In October, 1899, the same author (20) in another paper reviewed the literature and presented the results of microscopic study in 2 other cases In the first of these, the palmar fascia was thickened and the process involved the skin He noted particularly the absence of sweat glands in the involved skin and increased thickness of the stratum corneum The palmar fascia was made up of dense fasciculi of white fibrous tissue Toward the wrist this band was acellular and avascular but in other places there was marked proliferation of connective tissue cells and capillaries In the second case the palmar fascia was merely one dense fibrous band which contained numerous nuclei, but few blood vessels This writer described the lesion as essentially a hypertrophy of connective tissue He stated that during an early or developing period the cellular or vascular elements occur in great abundance but at a later stage when the lesion is fully developed and stationary, the cells and vessels diminish leaving the abnormal tissue, a dense mass of connective tissue which is similar to the pre-existing normal palmar fascia

In 1897, Anderson considered the condition to be inflammatory hyperplasia or neoplastic growth which began in the skin and subcutaneous tissues of the palm and by a process of nuclear proliferation spread along the course of the blood vessels, replacing the adipose tissue and, secondarily, involving the palmar fascia Ledderhose (13), in 1897, described a similar pathological condition in the plantar fascia, which he termed "plantar fasciitis" In another article on palmar fasciitis in 1920, the

same author (14) ascribed Dupuytren's contracture to a chronic proliferative process without inflammation

In 1902, Janssen studied the microscopic anatomy of the hand in 7 cases and gave a comprehensive description of his observations He noted the early thickening of the palmar fascia, then the formation of small knots, and finally, the contracture of the fascia and adherence of the skin to the fascia On microscopic examination he described the process as a proliferation of fibrous tissue from multiple foci which extended down to, and involved, the tendon sheaths He described the close resemblance microscopically between the cellular fibrous tissue and fibrosarcoma, he even noted the occasional presence of mitotic figures He concluded, however, that Dupuytren's contracture is not a neoplastic process nor an inflammatory process as there are no signs of inflammation and the lesion is purely a hypertrophic process

In 1918, Coenen made a complete and detailed review of the literature and concluded that Dupuytren's contracture is chronic inflammation of the superficial palmar aponeurosis with vascularization and proliferation of new cells He did not report any studies or observations on cases of his own

In 1920 and 1921, Krogus (11, 12), from observations on his own patients, made a distinction between new and old cases In the new cases, newly formed connective tissue appeared, in the old cases, the bands were hard, strong, and hyalinized He ascribed the contracture to the proliferation of embryonic rests of primitive muscles of the palm—the flexores breves manus superficiales

In 1928, Klé reviewed the literature and reported his observations in 10 cases He noted the changes described by previous authors He concluded that the condition is a thickening of the palmar aponeurosis as the result of the new formation of connective tissue The cellular part of the newly formed connective tissue often resembles fibrosarcoma Some investigators, he stated, have noted lymphocytic infiltration, but in his cases this was observed only rarely He did not believe, therefore, that the condition was inflammatory He stated that although some portions do re-

THE ETIOLOGY AND PATHOLOGY OF DUPUYTREN'S CONTRACTURE

HENRY W MEYERDING M.D., F.A.C.S JOHN R. BLACK, M.D. and
ALBERT C. BRODERS, M.D. Rochester Minnesota

THE etiology of Dupuytren's contracture has not been established definitely. In previous publications, one of us (Meyerding 15-18) has reported his clinical, surgical, and postoperative observations. Available tissue removed at operation has been examined microscopically in order to determine the pathological changes. We recognized, as other pathologists have that the thickened and contracted palmar fascia caused the deformity. The fascia in these cases is characterized by definite proliferation of its fibrous components. A search was made for the factors involved in the production of this proliferation and in adjacent palmar tissues, areas of increased vascularity and lymphocytic infiltration were discovered. Although there is evidence that heredity and trauma may play a rôle we believe that the inflammatory reaction noted is of prime importance in the etiology of Dupuytren's contracture.

In 1831 Dupuytren gave his first description of what he termed "*retrocion permanente des doigts*" (permanent contracture of the fingers) a condition which has subsequently been named after him. Although Dupuytren was not the first to recognize that the palmar fascia was chiefly responsible for the flexion deformities of the fingers, he described the gross pathological changes so clearly and so well that posterity has seen fit to do him honor by giving his name to this clinical entity. He observed from his dissections that the skin of the palm had small hard knots and wrinkles which disappeared when the skin was dissected from the palmar fascia. The palmar fascia itself was hard and thick, diminished in length, and was under tension. The prolongations from the fascia distally ran to the sides of the proximal phalanges of the fingers. The

contracture of these prolongations of the palmar fascia produced flexion of the fingers. Examination of tendons and joints revealed them to be entirely normal.

The descriptions of the microscopic pathology given by the early authors were meager. In 1877 P. Richer dissected the left hand in a case of bilateral Dupuytren's contracture. He stated that the skin was firmly adherent to the underlying fascia, but was scarcely changed microscopically. The superficial fascia was thickened, hard, and shortened owing to an increase in the number and size of the elastic and collagen fibers. He concluded that the palmar fascia was the only structure altered. No signs of inflammation were noted, but he classified the changes as the same as those in chronic articular rheumatism. In 1882, F. Chevrot made a study of the histological changes in Dupuytren's contracture. He noted the thickened palmar fascia and the absence of the normal adipose tissue separating the fascia from the skin. In addition however he described a thickening of the epidermis, which he attributed to the protection of the surface epithelium from friction as a result of the contracture. He noted a thickening of the lining of the sweat glands.

Langhans, in 1887 apparently made a thorough pathological study of Dupuytren's contracture for many of his contemporaries and later writers have quoted from his work (3, 4, 9, 10, 13). He is credited with the following observations on the pathogenesis of Dupuytren's contracture. It is an inflammatory and proliferative process which begins in the interstitial connective tissue and in the adventitia of the blood vessels. This process involves the palmar fascia and leads to an increase in the number and thickness of the bands of connective tissue. In the fascia the number of nuclei is increased but they also occur in scattered groups throughout the fat and interstitial con-

In 1920 and 1921, Krogius (11, 12), from observations on his own patients, made a distinction between new and old cases In the new cases, newly formed connective tissue appeared, in the old cases, the bands were hard, strong, and hyalinized He ascribed the contracture to the proliferation of embryonic rests of primitive muscles of the palm—the flexores breves manus superficiales

In 1928, Iklé reviewed the literature and reported his observations in 10 cases He noted the changes described by previous authors He concluded that the condition is a thickening of the palmar aponeurosis as the result of the new formation of connective tissue The cellular part of the newly formed connective tissue often resembles fibrosarcoma Some investigators, he stated, have noted lymphocytic infiltration, but in his cases this was observed only rarely He did not believe, therefore, that the condition was inflammatory He stated that although some portions do re-

semble a neoplasm the anatomical findings are against it. It is not fibroma because the process is multifocal and diffuse nor is it sarcoma because local infiltration and metastases do not occur and only a few mitotic figures are present. He proposed to call it a chronic hyperplastic process resulting in fibrosis of the palmar fascia.

More recently other authors (4, 8, 21) have reviewed the literature but few have investigated the microscopic pathology and little has been added to the observations of the earlier writers.

There has been great unanimity of opinion regarding the nature of the pathological changes in the palmar fascia. It becomes hard and thickened and presents varying degrees of cellular proliferation. The descriptions of changes in the other tissues of the palm are far from consistent. Some investigators have noted involvement of the skin and subcutaneous tissue others have not. Many have noted the formation of new connective tissue and blood vessels, but most authors have denied the presence of leucocytes in the affected tissues.

The etiology of Dupuytren's contracture has long been a problem to the medical world. We do not wish to discuss it in detail but wish merely to point out the relationship of the histological changes to the etiology. Dupuytren himself expressed the belief that local trauma played a large part in the production of contracture of the palmar fascia because, in his experience it was more common in manual laborers. Contemporary writers associated contracture of the palmar fascia with gout, but at the same time they confused gout with various forms of arthritis (chronic infectious arthritis, senescent arthritis, and so forth). Many investigators have noted the association of contractures of the fingers with contractures of the palmar fascia following lesions of the central nervous system, such as tabes dorsalis, multiple sclerosis, syringomyelia, and injuries to the spinal cord and also of the peripheral nerves after fractures and other trauma. Heredity has long been known to be an outstanding predisposing factor. Chronic infection has long been a subject of much debate. The chief opposition has been based on the lack of evi-

dence of inflammation in the affected tissue as evidenced by leucocytic infiltration.

HISTOLOGY OF THE NORMAL SKIN OF THE PALM AND FASCIA

Before considering the pathological changes which occur in the palm in Dupuytren's contracture we shall review briefly the normal histology. In order better to compare the pathological changes (Fig. 1) The normal skin of the palm has a similar structure to skin of other parts of the body. It differs in certain respects in that it contains no hair follicles or sebaceous glands and deep in the subcutaneous tissue there is a dense layer of fascia, the palmar fascia.

The skin consists of three main layers: the epidermis, the dermis, and the subcutaneous tissue. The epidermis is made up of stratified epithelium in various stages of its growth as the cells grow from the basal layer outward through the prickle-cell stage, then become keratinized and finally are shed as dead scale epithelium.

The dermis, or corium, is that portion of the skin which lies immediately beneath the epidermis and carries the nerves and blood vessels which supply the skin. The dermis is made up of two strata, a deeper reticular layer and a superficial papillary layer. The surface of the papillary layer presents numerous conical elevations, the papillae of the corium which project into the under surface of the epidermis. These papillae are abundant in the palm. They consist of a fine supporting network of connective tissue for the finer branches of the cutaneous blood vessels and nerves. A few wandering cells and lymphocytes may be seen particularly just beneath the basal layer of the epidermis. The deeper portion of the corium consists of interlacing bundles of connective tissue fibers which form a moderately loose network. These bundles are much coarser than those of the papillary layer and seem to pursue a wavy or spiral course. This loose regular arrangement of collagen bundles gives to the reticular layer the appearance of having been braided or woven. It is this loose elastic structure of the derma which allows the skin to stretch and bend with every movement of the hand. The reticular layer contains the

larger blood vessels of the corium and many small nerve trunks. The secreting portion of many of the sweat glands lies in the deeper portion of the reticular layer, most of these glands, however, lie in the superficial layers of the subcutaneous tissue.

The subcutaneous tissue consists of a coarse network of narrow strands of connective tissue, which pass between the reticular layer and the palmar fascia. The meshes of this network are occupied by lobules of adipose tissue. The palmar fascia consists of a thin layer of dense connective tissue. The collagen fibers are straight and are packed close together in parallel bundles. The fascial bands form a sheath of tissue parallel to the surface of the skin and are connected to the skin superficially and to the deeper structures by thin strands of dense, strong connective tissue. The nuclei in the connective tissue of the fascia are few, very small and elongated as they lie between the collagen fibers.

Connecting and filling the spaces between the various layers of the skin, subcutaneous tissue and fascia is a very loose network of connective tissue made up of loose bundles of wavy collagen fibers. It forms the supporting tissue for the blood vessels and nerves as they lie deep to the palmar fascia. The few nuclei of the connective tissue in this interstitial tissue are small and stellate. Only an occasional wandering cell is seen in the normal connective tissue.

MATERIAL STUDIED

In 1936, one of us (Meyerding, 16) reported observations made on 448 hands of 273 patients with Dupuytren's contracture. Eighty-four, 31 per cent, of the patients were subjected to operation. The material studied in the present investigation consisted of the available specimens removed at operation in this series of cases as well as others obtained since 1935. Specimens from 57 cases were studied, the cases were encountered in the period from January, 1913, to July, 1938 inclusive. These specimens, in the main, consisted of the contracted palmar fascia, in many cases, the entire fascia, in others, just the contracted bands. In some cases, the overlying skin was removed still attached to the fascia, in many specimens

Fig 1, left. Normal skin showing the various layers including the palmar fascia. $\times 11$.

Fig 2. Skin in Dupuytren's contracture showing thickening of the epidermis with hyperplasia of all the zones. $\times 21$. The normal structure of the corium is completely changed, the papillary layer is distorted and there is a marked perivascular lymphocytic infiltration in all layers, this is most marked in the papillary zone. The regular pattern of the reticular layer is completely disrupted. The subcutaneous tissue has disappeared and the palmar fascia is adherent to the deeper layers of the skin. Sweat glands are entirely absent.

in which all the layers of the skin were lacking, the deeper layers of the skin were present and in these the sweat glands and other structures could be studied. Many of the studies made in the past were incomplete because the specimens available were only small fragments of contracted fascia. Some authors, it is true, studied the entire hand at necropsy, but the number of such cases is small. On the whole, the specimens studied in our series probably represent more complete samples of the palmar fascia and neighboring tissues than those studied by early pathologists. This fact may account for the failure of these men to observe some of the tissue changes which will be described by us in the following paragraphs.

The tissues were fixed in 10 per cent formalin, sectioned with the freezing microtome, and stained with hematoxylin and eosin. Sections were taken from various places on the tissue removed from each patient, in order to select the most characteristic. That is, cross sections and longitudinal sections were made through the fascia and skin including any of the nod-

semble a neoplasm the anatomical findings are against it. It is not fibroma because the process is multifocal and diffuse nor is it sarcoma because local infiltration and metastases do not occur and only a few mitotic figures are present. He proposed to call it a chronic hyperplastic process resulting in fibrosis of the palmar fascia.

More recently other authors (4, 8, 21) have reviewed the literature but few have investigated the microscopic pathology and little has been added to the observations of the earlier writers.

There has been great unanimity of opinion regarding the nature of the pathological changes in the palmar fascia. It becomes hard and thickened and presents varying degrees of cellular proliferation. The descriptions of changes in the other tissues of the palm are far from consistent. Some investigators have noted involvement of the skin and subcutaneous tissue others have not. Many have noted the formation of new connective tissue and blood vessels, but most authors have denied the presence of leucocytes in the affected tissues.

The etiology of Dupuytren's contracture has long been a problem to the medical world. We do not wish to discuss it in detail but wish merely to point out the relationship of the histological changes to the etiology. Dupuytren himself expressed the belief that local trauma played a large part in the production of contracture of the palmar fascia because in his experience it was more common in manual laborers. Contemporary writers associated contracture of the palmar fascia with gout but at the same time they confused gout with various forms of arthritis (chronic infectious arthritis, senescent arthritis, and so forth). Many investigators have noted the association of contractures of the fingers with contractures of the palmar fascia following lesions of the central nervous system, such as tabes dorsalis, multiple sclerosis, syringomyelia, and injuries to the spinal cord and also of the peripheral nerves after fractures and other trauma. Heredity has long been known to be an outstanding predisposing factor. Chronic infection has long been a subject of much debate. The chief opposition has been based on the lack of evi-

dence of inflammation in the affected tissue as evidenced by leucocytic infiltration.

HISTOLOGY OF THE NORMAL SKIN OF THE PALM AND FASCIA

Before considering the pathological changes which occur in the palm in Dupuytren's contracture we shall review briefly the normal histology in order better to compare the pathological changes (Fig. 1). The normal skin of the palm has a similar structure to skin of other parts of the body. It differs in certain respects in that it contains no hair follicles or sebaceous glands and deep in the subcutaneous tissue there is a dense layer of fascia, the palmar fascia.

The skin consists of three main layers: the epidermis, the dermis, and the subcutaneous tissue. The epidermis is made up of stratified epithelium in various stages of its growth as the cells grow from the basal layer outward through the prickle-cell stage then become keratinized and finally are shed as dead scaly epithelium.

The dermis, or corium, is that portion of the skin which lies immediately beneath the epidermis and carries the nerves and blood vessels which supply the skin. The dermis is made up of two strata, a deeper reticular layer and a superficial papillary layer. The surface of the papillary layer presents numerous conical elevations, the papillae of the corium which project into the under surface of the epidermis. These papillae are abundant in the palm. They consist of a fine supporting network of connective tissue for the finer branches of the cutaneous blood vessels and nerves. A few wandering cells and lymphocytes may be seen particularly just beneath the basal layer of the epidermis. The deeper portion of the corium consists of interlacing bundles of connective tissue fibers which form a moderately loose network. These bundles are much coarser than those of the papillary layer and seem to pursue a wavy or spiral course. This loose regular arrangement of collagen bundles gives to the reticular layer the appearance of having been braided or woven. It is this loose elastic structure of the dermis which allows the skin to stretch and bend with every movement of the hand. The reticular layer contains the

ules that were present. It was often impossible to distinguish in the gross specimen the digital from the carpal fascia.

PATHOLOGICAL FEATURES

The descriptions of the pathological changes in Dupuytren's contracture even from the earliest times have emphasized the fibrosis and contracture of the palmar fascia. The changes which were observed in the skin and subcutaneous tissue were regarded as secondary to the contracture of the fascia. Certainly the gross deformity and chief manifestations of the disease are due to contracture of palmar fibrous tissue of which the palmar fascia is the chief constituent.

It is difficult to determine in which tissue or tissues the primary effect takes place because it is only rarely that tissue is obtained in a very early stage of the disease. Recently after the present review had been completed a patient was seen with bilateral plantar fasciitis, the analogue of Dupuytren's contracture in the foot. In this case the plantar fascia presented all the appearances of normal fascia, microscopically. The collagen fibers were closely packed in parallel bundles and were hyalinized. The cells in the connective tissue of the fascia were mature small flat tened and squeezed in between the fibers of the fascia. However in the loose connective and adipose tissue between and around the fascial bundles were numerous new capillaries each of which was surrounded by a large num-

ber of lymphocytes. A specimen of skin was not obtained, but clinically it was unchanged. In early cases of Dupuytren's contracture however the palmar fascia is tightened but even before any contracture takes place the skin becomes thickened and puckered. It is bound down to the underlying tissue and is no longer freely movable. In most instances, we observed that our sections revealed involvement of both the adipose tissue and the palmar fascia. In all cases in which the overlying skin was available for study definite pathological changes were noted in it. It is probable therefore that the disease begins in the interstitial connective tissue and usually spreads to involve all the tissues of the palm down to the deep structures: tendon sheaths, nerves, and blood vessels.

It is a peculiar fact that the disease process should affect the ulnar aspect of the palm more than any other portion. Although the skin, subcutaneous tissue and palmar fascia are affected yet in any one case only portions of the skin or other tissues are involved. Certainly the skin over the thenar eminence and proximal portion of the palm usually is not affected and this also applies to the subcutaneous tissue and palmar fascia.

In 10 cases, portions of skin in the region overlying the contracture were available for study. In others, although the outer layers were absent, frequently the deeper layers of the corium were adherent to the contracted tissue. The layers chiefly affected were the

reticular and papillary zones of the corium and in all the available cases an increase in the number and density of the connective tissue fibers was noted (Fig 2). The reticular zone loses its regular arrangement and loosely woven structure. The fibers, normally running parallel to the surface, become dense masses of connective tissue running in every direction. This accounts for the clinical loss of elasticity of the skin. The papillae of the skin are also changed and become irregular. There is hypertrophy of the epidermis with marked proliferation of all the layers. Numerous new capillaries are seen in the corium surrounded by small groups of lymphocytes. The number of lymphocytes increases in the papillary layer of the corium just beneath the basal layer of the epidermis.

In normal skin the line of demarcation between the dermis and subcutaneous tissue is clearly defined. In this region are found the secreting portions of the sweat glands. In advanced cases of Dupuytren's contracture evidence of subcutaneous adipose tissue is not revealed (Fig 2) and sweat glands are rare or completely absent. Dense parallel strands of fascia lie just beneath and closely adherent to the reticular layer of the dermis. In less advanced cases (Figs 3 and 4) the sweat glands are surrounded by fibrous tissue and numerous lymphocytes, the latter are also seen between the acinar lobules of the gland itself (Fig 5).

The deeper layers of the subcutaneous tissue show an increase in the size and number of the connective tissue bands which normally separate the lobules of fat. There is an increase in the number of capillaries in the interstitial connective tissue and the capillaries are surrounded by lymphocytes. The more advanced the disease the greater is the degree of fibrosis. Infiltration seems to precede the fibrosis (Figs 3, 4, and 5) since the new capillaries and lymphocytes are more numerous about the still unchanged fat cells. The fat appears to be absorbed or destroyed by this process, then new connective tissue forms and obliterates the capillaries and the lymphocytes also disappear. The palmar fascia is separated from the nerves and vessels to the fingers by a layer of adipose tissue. This fatty tissue may also be involved and the thickened

and scarred fascia is closely adherent to the deeper structures. For this reason, nerves and blood vessels were occasionally found embedded in the contracted fascia.

In 24 of the 57 cases, there was definite lymphocytic infiltration of the skin or subcutaneous tissue, only occasionally were plasma cells or polymorphonuclear leucocytes noted. The lymphocytes were commonly found around the sweat glands, blood vessels, and fat cells. The other components of this process, new connective tissue and capillaries were noted in various degrees in most cases and on this basis each case was graded according to the activity of this process.

The palmar fascia gives a picture entirely different from that described in the other tissues, but the changes in this structure are the ones that have been commonly described as characteristic of Dupuytren's contracture. Proliferation of new capillaries and perivascular infiltration of lymphocytes are almost entirely lacking in the palmar fascia itself. Only occasionally are new capillaries seen and in no instance were lymphocytes seen in the fascia. The characteristic change is the proliferation of fibroblasts in the nodules of the contracture. These fibroblasts are round, oval, or spindle-shaped with pale staining nuclei and tend to grow in masses with their long axis, parallel to one another. In very cellular areas (Figs 6, 7, 8, 9, and 10) where the nuclei are closely packed, many mitotic figures may be seen. In this tissue all stages can be demonstrated from those just described to that in which the collagen fibers lie packed together so tightly that the thin, flattened nuclei can scarcely be distinguished (Fig 11), the fibers in such portions of the fascia are frequently hyalinized. The marked cellular proliferation is usually seen in the thickened areas of the fascia which correspond to the base of the fingers in the palm. As new fibrous tissue is deposited and contracts, the fibrous connective tissue cells become mature and flattened, forming streaks through the fascia as shown in Figure 9.

We have assumed that the cellular nature of the fascia described indicates the activity of the proliferative process and, therefore, the degree of maturity of the connective tissue was graded on a basis of 1 to 4. The least ma-

Fig. 6. Nodule from Dupuytren's contracture. $\times 185$. Maturity of connective tissue of palmar fascia is grade 2; there is marked cellularity but the cells are smaller and there are more intercellular fibers than in grade 1. Not partially destroyed fat lobules. Area marked X is shown under high-power magnification in Figure 7 from this Figure 6.

ture process in which the tissue was very cellular was graded 1 (Fig. 12) the most mature in which the nodules were very small and very few in number when compared to the collagen fibers, was graded 4 (Fig. 11). Intermediate

degrees were graded 2 (Figs. 6 and 7) and 3 (Fig. 13).

A specimen of palmar fascia was removed surgically from 63 hands belonging to 57 patients. Sixty-one specimens were studied; the maturity of connective tissue was graded and the degree of the inflammatory reaction was estimated. In all cases the degree of inflammatory reaction was mild. The maturity of connective tissue was grade 1 in 9 cases, grade 2 in 19 cases, grade 3 in 15 cases and grade 4 in 18 cases. The cases studied in this group, therefore, tended to have a mature degree of connective tissue. When the relationship of the duration of the contracture to the degree of maturity of the connective tissue was considered, in the cases of longer duration the degree of maturity tended to be greater but there was a wide variation in individual cases. Little relationship was noted between the age of the patient and the grade of maturity of the fascia. The degree of contracture seems to depend more on the duration of the process than on the grade of maturity. No definite correlation was found between the degree of contracture and grade of maturity of fascia.

Fig. 10. Cellular nature of tissue from Y in Figure 9. Note mitotic figures. $\times 750$.

Recurrence of contracture occurred in 9 cases and when the tissue from these cases was studied it was found that the average grade of maturity for the group was 1 to 2. This represents a much less mature type of connective tissue than in the series as a whole and indicates a more active tissue. On the other hand, a significant increase in the degree of activity of inflammatory changes was not noted.

Occasionally patients with Dupuytren's contracture complain of soreness and tenderness of the affected region although the usual complaints are thickening of the palm, "callus" contracture of a finger or a prickling sensation. It was thought that in cases in which soreness and tenderness of the palm were present greater degrees of inflammatory activity would be found than in other cases. Our studies, however, did not bear this out.

COMPARISON OF CLINICAL BEHAVIOR AND PATHOLOGICAL PICTURE

The estimation of the inflammatory reaction and the activity of the proliferation of connective tissue in the fascia, which did not necessarily parallel one another, enabled us to compare the clinical behavior with the pathological picture. One particular conception of Dupuytren's contracture interested us particularly and that was the relationship of the so-called green and mature stages to the prognosis. Our studies bear out the idea that there are various degrees of activity in the process and, in the recurrences noted, the fascia tended to be immature. The number of cases of recurrence studied is too small, however, to state conclusively that in cases in which histological examination reveals a low grade maturity of the fascia recurrence is more likely to occur than in those in which higher grades of maturity are found. In the majority of our cases contractures were well established for they had been present for several years, microscopic examination disclosed in most cases a mature type of connective tissue. Therefore if our theory is correct, it would be natural to assume recurrences to be few in this series.

SUMMARY AND CONCLUSIONS

In the past, other investigators have focused their attention on the palmar fascia to the ex-

Fig 11

Fig 12

Fig 13

Fig 11 Palmar fascia, the maturity of the connective tissue is grade 4 $\times 130$. Hyalinized fascia. The fibers lie closely packed in parallel bundles, the nuclei can scarcely be distinguished. They are few in number, flattened and very small.

Fig 12 Palmar fascia, maturity of connective tissue is grade 1, $\times 67$, very cellular fascia with few intercellular collagen fibers. Figures 6 and 7 in which the maturity of the connective tissue is grade 2 should be noted, too.

Fig 13 Palmar fascia, maturity of connective tissue is grade 3 $\times 130$. Nuclei are smaller and flatter than in Figures 6, 7, and 12 in which the maturity of the connective tissue is graded 2. There is a large amount of intercellular collagen.

clusion of the surrounding tissue and have not described the signs of inflammation, proliferation of capillaries and fibroblasts with marked perivascular lymphocytic infiltration. This inflammatory reaction affects chiefly the skin, subcutaneous tissue, and interstitial connective tissue. The palmar fascia is remarkable for the fact that within its fibers there is evidence of an active proliferation of fibroblasts without other signs of inflammation. The process progresses through the cycle of fibroblastic proliferation, and then deposition of collagen fibers which contract and compress the fibroblasts and the final picture of avascular scar tissue result.

This study further demonstrates the fact that Dupuytren's contracture is not merely a disease of the palmar fascia, but involves all structures from the skin down to the tendon sheaths. It is difficult, therefore, to see how

subcutaneous tenotomy could give consistently good results. On the other hand excision of the mass of scar tissue requires a high degree of surgical skill as emphasized by one of us in a previous paper (17). In cases in which the excised tissue gives evidence of active inflammatory reaction or immature fibrous tissue in the fascia, we believe the likelihood of recurrence is greater.

From the point of view of pathological diagnosis, we wish to point out the danger of confusing Dupuytren's contracture—a benign process, with fibrosarcoma. Errors in such a diagnosis have in the past given rise to tragic results. Although certain portions of the tissue removed for Dupuytren's contracture do resemble fibrosarcoma on superficial examination and may even contain numerous mitotic figures, there are many points of difference. Dupuytren's contracture is a diffuse multifocal process; the sarcoma-like areas are located in the palmar fascia at the site of the nodules which are so characteristic of the disease. Surrounding these nodules is dense fibrous tissue. The nuclei are pale staining and regular in shape and size. Local infiltration by these young cells and metastasis do not occur all of which points are against a malignant lesion.

We have studied the microscopic sections of the palmar fascia in 57 cases of Dupuytren's contracture and we have formed the opinion that the pathological picture is best explained on the basis of a chronic inflammatory process.

TERATOMA TESTIS

Survey of Thirty-seven Autopsy Records

BENJAMIN S. BARRINGER, M.D., F.A.C.S., and DAVID EARL, M.D.
New York, New York

TERATOMA testis is unique among all malignant tumors of the body in that a majority of teratomas have an absolute x-radiation sensitivity. That is, the primary tumors and their metastases have often regressed under external irradiation, and this regression has been permanent. We have had at the Memorial Hospital approximately 600 cases of teratoma testis. By means of high voltage roentgen therapy we have been able to double the cures of this highly malignant disease. At present our 5 year controls are 30 per cent.

Obviously there is much room for improvement.

We have been able to eliminate entirely the one major operation with its attendant mortality, the Chevassu-Hinman dissection of the retroperitoneal tissues with their lymph vessels and glands, which lie along the course of the spermatic vessels. Such a dissection is superfluous if there are no metastases present, and if they already exist then the procedure is inadequate. Deep roentgen therapy is far more efficient. The reasons for this inadequacy lie in the size of the metastases and the frequency with which crossed abdominal metastases occur.

The paucity of postmortem studies of teratoma testis is difficult of explanation. In order better to understand the course of this lesion when uncontrolled, this survey of autopsy material was made. The majority of cases in this series has had either surgical or irradiation treatment. However, therapy as applied to these cases is not the consideration of this review. The survey has been of vast importance in indicating a rational therapy for the future.

Age. The youngest patient was 9 months old—the oldest patient was 47 years, with an

From the Memorial Hospital

average age of 31.5 years. Only 36 cases were used in calculating the average age because one patient was a premature stillborn of 8 months.

Trauma. A history of trauma preceded the patient's observation of testicular enlargement in 6 cases. But the instances are woefully inadequate as to the exact site of the trauma, the appearance of the testicle, ecchymosis, swelling, etc., immediately following the trauma, and the sequence of events between the trauma and the appearance of the teratoma. We are quite sure we have never seen a case in which we have believed that there was even reasonably proved a connection between trauma and the causation of the teratoma.

Various types of teratoma testis. There were 10 cases, 27.0 per cent, of embryonal carcinoma with lymphoid stroma, 9 cases, 24.3 per cent, of embryonal carcinoma. These two classes comprising half of the cases are most radiosensitive.

There were 10 cases, 27.0 per cent, of embryonal adenocarcinoma, less sensitive to irradiation.

One case, 2.7 per cent, of teratomatous adenocystoma (adult teratoma), still less radiosensitive.

Three cases, 8.2 per cent, of chorionepithelioma, the least radiosensitive of all.

Four cases, 10.8 per cent, unclassified.

Site involved and cryptorchidism. The right testicle was involved 19 times, 51.45 per cent, the left testicle 18 times, 48.55 per cent. Abdominal cryptorchidism with teratoma occurred 4 times 10.8 per cent. Three of these abdominal testicles were unilateral with a teratoma of the retained testicle. One of these was in a stillborn child with no microscopic diagnosis. In one case there was bilateral cryptorchidism with teratoma on one side.

Aschheim-Zondek reaction This determination was made in 21 cases. It was positive in 18 cases, 85.7 per cent questionable in 1 case, and negative in 2 cases. Because of the various and inadequate methods used in determining the Aschheim-Zondek tests in the above cases these 85 per cent positive tests are probably not at all accurate. Drs. Dean and Temple, in a recent unpublished review of the Aschheim-Zondek test as applied to teratoma testis cases in the Memorial Hospital came to the following conclusions:

1 The test is inadequate as it has been done because at least 5 mice should be used per level.

2 The test cannot be used to determine the histological type, because there is no close correlation between the hormone level and the type. (Some cases show close correlation but many others show wide discrepancies.) The adult type when purely adult apparently shows a low level. The chorioncarcinomas are consistently high. The great majority of the embryonal carcinomas show levels below 1500 mouse units per liter. The embryonal adenocarcinomas show a complete range of levels from very low to very high.

3 The chief difficulty in attempting to study correlation between the histological type and the hormone level is that a large number of the tumors are mixed and complex. Therefore serial sections should be used in a study of this type. All types may be found in the same tumor thus complicating any attempt at correlation. A new classification is in order: such a new classification is obviously difficult to make.

4. The test is of definite value in predicting the prognosis, because in general, those with high levels die much sooner than those with low levels. Discrepancies are found, and therefore only general statements can be made. Because of the value in predicting prognosis, we believe the test should be made routinely.

5 Our study did not take into complete account the relation of prolans A and B. In the early years of the test, the erroneous assumption that a 1:5 ratio always existed between A and B was followed. This was advanced by Zondek. It seems in all probability

that the determination of prolans B is of more value than it has previously been suspected, and it probably always means a comparatively early fatal outcome. Further work must be done on this.

6 We believe, after an analysis of 203 cases, that values between 0 and 500 have the same significance.

Gynecomastia Gynecomastia was noted in 2 cases: 1 unilateral with secretion, 1 bilateral without secretion. In the unilateral case the histological diagnosis was fibrous mastitis. Both cases had positive reactions to the Aschheim-Zondek test.

Metastases Metastases from teratoma testis occur through both blood and lymph channels. In a very large percentage of our autopsy cases the metastases were by means of both channels.

Blood stream metastases This is through the spermatic artery to the renal artery or aorta and thence to the heart and lungs. Chorionepithelioma may metastasize entirely through the blood stream.

The history of a patient with chorionepithelioma seen at the Memorial Hospital last year demonstrates this:

B V, aged 30 years, was admitted to the Memorial Hospital, on July 20, 1939, with the following history: Two months before swelling of the left testicle occurred. One month prior to admission left orchidectomy was done. The diagnosis was chorionepithelioma of the testicle (corroborated in Memorial Hospital). The roentgenological report follows:

S. Submitted films of the chest reveal three rounded bonyless densities, measuring approximately one half inch in diameter in the right lower lung field, suggesting metastatic process. These densities are noted in the films dated June 30, 1939, and July 2, 1939. S. Submitted films of the dorsal vertebrae: lumbar vertebrae, pelvis, including greater portion of the upper shaft of the femora and skull, reveal no evidence of bone metastasis. N. adenopathy in neck. N. abdominal masses. Liver not palpable. Aschheim-Zondek test July 1939. Between 100 and 500 units prolans A per liter and August 12, 1939, 500 A and 100 B. Chest and liver radiated as follows: From six portals of entry—right upper chest anterior and posterior, right lower chest anterior and posterior, and liver anterior and posterior—50 r daily at 50 cm. until he received approximately 2500 r each area. Roentgenological examination of chest shows only the faintest suggestion of the upper of three previously discovered nodules in right chest.

Lymphatic metastases Ronviere¹ describes the lymphatics draining the testicle as follows

"All lymph trunks of the testicle eventually arrive at the posterior superior border of the organ and thence along the blood vessels of the spermatic cord

"The lymphatics accompany the internal spermatic artery and vein, and having arrived at the point at which these blood vessels cross the ureter, the testicular collecting trunks commence to separate from the spermatic blood vessels. They finally are drained by the abdomino-aortic nodes which run from the level of the renal vein to the bifurcation of the aorta

"The abdomino-aortic nodes are not the sole direct recipients of the lymphatics of the testicle. There are other lymph vessels that terminate in an external iliac node placed on the external iliac vein in front of the point where the latter is crossed by the ureter (The above applies to the testicle proper)

"The lymphatics of the epididymis terminate in the external iliac nodes

"The lymphatics of the ductus deferens anastomose with those of the epididymis at its origin and with the lymphatics of the seminal vesicles, the bladder, and of the prostate at its termination. The author also notes that the lymphatics of the ductus deferens empty into the external iliac and hypogastric nodes

"Supraclavicular nodes. The normal collateral branches of the thoracic duct are the efferent collecting trunks from the intercostal nodes on the course of which the juxtavertebral nodes are found. These collateral branches, instead of terminating in the thoracic duct, all open into an independent prevertebral collecting trunk, this collecting trunk is then joined to both ends of the thoracic duct by its two extremities only, the trunk terminating above directly in the jugulosubclavicular junction or in a node of the transverse cervical chain"

The practical application of this is that if there is a metastatic left supraclavicular node there is probably a metastatic chain of nodes all along the course of the thoracic duct. This is not always the case as I have seen a left supraclavicular metastatic node disappear under irradiation and the patient remain well in spite of the fact that there was no irradiation of the thoracic duct

Because the lymphatics of the testicle generally drain into the abdomino-aortic nodes we most frequently find the first metastasis in the upper abdomen above the bifurcation of the aorta. This does not preclude the possibility of a lower abdominal metastasis as these are the glands (external iliac) which drain the

epididymis. The teratoma originating in the rete testis, at the junction of the testicle proper and the epididymis, may grow either toward the testicle or toward the epididymis, or involve both

The regional node involvement of the 37 cases, expressed in percentage, is as follows: inguinal, 4 cases, 10.8 per cent, pelvic or iliac, 14 cases, 37.9 per cent, lumbar, 20 cases, 54.16 per cent, celiac, 21 cases, 56.87 per cent, mesenteric, 7 cases, 18.95 per cent, mediastinal, 18 cases, 48.7 per cent, bronchial, 13 cases, 35.2 per cent, cervical, 13 cases, 35.2 per cent

A tumor of the testis rarely metastasizes to the inguinal nodes unless it has perforated the tunica vaginalis or capsule of the testicle. In Cases 4, 26, and 31 these nodes appeared after operation. This is significant as we believe that inguinal node involvement is almost always the result of cutting into the teratoma with the resultant implanting of tumor cells in the operative wound and a secondary involvement of the inguinal glands. In Case 16 the inguinal nodes were contralateral only. The explanation of this finding is not clear. However, this patient had generalized metastases

In 10 cases, or 27 per cent, there was node involvement which extended from the lumbosacral promontory to the left supraclavicular region

In 5 cases, or 13.5 per cent, in which the abdominal and mediastinal nodes were involved, the left supraclavicular nodes were not palpable

The mediastinal nodes were involved in 48.74 per cent of the cases. In the chest films observed there was no hint of mediastinal involvement in less than half of the cases

The bronchial and cervical nodes were each involved in 13 cases, or 35.2 per cent, but involvement in both regions occurred only 7 times, or in 18.95 per cent

In 7 cases in which the right testicle was the primary focus there were left sided supraclavicular so called signal nodes. In 6 cases in which the primary focus was in the left testicle there were left signal nodes

In many cases the center of the nodes or metastatic foci, especially those in the liver,

¹Anatomy of the Human Lymphatic System, 1938

were broken down and hemorrhagic. In 5 cases of this type the peritoneal cavity contained bloody fluid in amounts up to 3000 cubic centimeters. This observation has been made at the operating table and may be very puzzling.

Gross metastasis to the head and neck. In 3 cases there was intracranial disease which did not involve the brain (meninges). In 3 other cases the brain was involved, which gives 16.24 per cent with intracranial involvement. This region was examined in less than half of these cases. This figure therefore, would be materially increased if the actual number of cranial examinations was known.

In Case 17 the spinal cord was involved. This case has been reported by Kennedy and Stevenson.¹ The thyroid was involved by metastatic disease only once. It being the only cervical structure involved other than lymphoid tissue.

Gross metastasis in the thorax. The lungs were involved in 29 cases 78.37 per cent. The pleura was involved in 14 cases, 37.9 per cent. In cases of pulmonary metastasis the mediastinal nodes were involved 16 times 55.1 per cent. The bronchial nodes were involved 13 times, 44.9 per cent, when the lungs were involved.

In 2 cases 5.4 per cent, there was bilateral hemothorax. In 2 cases, 5.4 per cent, there was unilateral hemothorax. In 1 case there was bilateral chylous thorax. Obstruction of the thoracic duct does not always result in chylous fluid accumulation because this may be conducted to the blood stream by accessory ducts.

In 2 cases there was a discrete metastatic focus within the chest wall. In 2 cases there was intravascular extension into the right auricle. This will be referred to later. In 2 cases the presence of pulmonary tuberculosis was noted.

In a surprising number of cases the diagnosis following first admission to a hospital is pulmonary tuberculosis because of the cachectic appearance, weight loss, night sweats, loss of appetite, cough and eventually blood stained sputum. Most of these cases showed no evidence of tuberculosis at postmortem exami-

nation and the clinical picture could be readily explained by metastatic teratoma testis.

Gross metastases were found in the abdomen in the following locations: diaphragm, 4 cases, 10.8 per cent; liver 28 cases, 75.8 per cent; spleen, 4 cases, 10.8 per cent; pancreas, 3 cases, 8.2 per cent; kidneys, 6 cases, 14.3 per cent; adrenals, 4 cases, 10.8 per cent; retroperitoneal mass, 22 cases, 59.57 per cent; gastro-intestinal tract, 2 cases, 5.4 per cent; genito-urinary tract, excepting kidneys, 4 cases, 10.8 per cent.

Where there was pulmonary involvement—29 cases—the liver was involved in 22 cases, or 75.86 per cent. The liver was involved in only 6 cases, or 21.42 per cent of the cases without lung involvement.

Liver involvement. Metastasis to the liver in most cases, must be blood borne. Therefore, there is no relation between the liver metastasis and the site of the primary tumor. This is borne out by the record. In 28 cases in which tumors were found in the liver the right testicle was the primary focus in 13 and the left testicle in 15 cases. This factor is extremely significant and to us an unexpected finding.

The gastro-intestinal tract was involved once by multiple discrete lesions and once by extension from a retroperitoneal mass into the duodenum.

The genito-urinary tract was involved intrinsically in 9 cases, or 24.3 per cent. The kidney parenchyma was involved by metastasis 4 times and by extension from a retroperitoneal mass once. Twice the involvement was bilateral and thrice unilateral. Frequently the kidney is embedded in a retroperitoneal mass but its capsule is a pretty effective barrier in preserving the integrity of the kidney. The kidney was hydronephrotic by pressure of the tumor either upon the ureter or upon the kidney pelvis, four times.

In one case metastatic teratoma testis which involved the kidney parenchyma grew into the renal vein whence it extended into the inferior vena cava and spread superiorly into the right auricle and inferiorly into the right common iliac vein. In this same case

Fig. 1. Case R.R.W. Diagnosis: Primary embryonal adenocarcinoma with lymphoid stroma. Autopsy findings: Signal node disease, lungs riddled, pleura involved, mediastinal nodes, gynecomastia, liver metastasis, retroperitoneal mass extended from pelvic brim upward.

Fig. 2. Case K.H. Diagnosis: Primary embryonal adenocarcinoma. Postmortem examination revealed the following: Pulmonary disease, liver disease, retroperitoneal mass, invasion of duodenum, thrombosis of cavae, mesenteric nodes.

CASE R. R. W. aged 33 years, was first seen at the Memorial Hospital, October 1933, with the following history: definite trauma to right testicle in 1922. Three years previously the right testicle became hard with no pain or swelling. Two months before he first noted nodes in the left side of the neck and gradual enlargement of the right testicle. He developed a productive cough with blood stained sputum. This was shortly followed by severe persistent backache. Seven weeks before he first noticed bilateral painless enlargement of the breasts without secretion. He lost 30 pounds in weight in a period of 2 months.

The Aschheim-Zondek test revealed a high prolactin content. A positive Wassermann reaction was obtained in 1933 and treatment was instituted.

Postmortem examination was made on November 1934.

Patient was a slightly emaciated white male with recent operative scar in the right groin. The right testicle had been removed. A bulky mass of tissue was present in the left neck. Both breasts were enlarged by palpable masses. The surface of the lungs was roughened as a result of studded areas of metastasis. The cut surface of the lungs showed marked congestion and the entire tissue of both lungs was riddled with metastatic areas from 0.5 to 3.0 centimeters in diameter. The liver was somewhat enlarged, congested, and contained two tumor areas. One of these was visible on the surface. Each measured about 0.5 centimeter in diameter both appeared hemorrhagic. The kidneys showed no abnormalities. The right testicle showed no abnormality. A disease as found at the site of the

left testicle which had been removed. Examination of the lymph nodes showed large tumor mass about 20 by 3 centimeters in retroperitoneal position extending from the pelvic brim along the vertebral column. The mass protruded more to the right than left side. The cut surface showed the same hemorrhagic areas as found in the lungs. Enlarged mediastinal nodes were found that contained tumor tissue, some measuring 3.0 centimeters in length. The mass of nodes in the left neck also contained the same type of tissue as the others. The brain showed no evidence of metastasis, except for small nodules. Tissue was removed from each breast; it was tough, fibrous, and of a shaggy structure.

The anatomical diagnosis was teratoma of the right testicle with metastasis to the lymph nodes, lungs, liver and arachnoid.

The microscopic examination showed embryonal adenocarcinoma. The liver metastases showed change in structure more diffuse, some giant cells but there was no suggestion of chorionepithelioma. The breast showed gynecomastia. The opposite testis showed no Leydig cell hyperplasia.

CASE K. H. aged 34 years, was first seen at the Memorial Hospital July 1934, with the following history: Patient lost 60 pounds in the past year. Two months ago a gastro-intestinal series as reported as normal (Lenox Hill). One month ago patient first noted a mass in the right side of the abdomen. Three weeks ago laparotomy (Philadelphia) revealed an inoperable retroperitoneal, right tumor just beneath the duodenum. The pan-

Fig. 3 Case 3 I H. Diagnosis Primary diffuse embryonal carcinoma. Autopsy findings: Signal node involved lungs riddled with miliary metastases. Large tracheo-bronchial nodes eroded trachea causing subcutaneous emphysema. Liver metastases. Wall of left ureter chain of nodes from bifurcation of aorta to left supraclavicular.

Fig. 4 Case 9 T C. Diagnosis Primary diffuse embryonal carcinoma. Autopsy findings: Disease in lung and pleura, disease in liver, retroperitoneal nodes causing hydroureter.

creases were not involved. No gynecomastia was noted. No Aschheim-Zondek test was made. The right testicle was small, hard and nodular—must have been the same at time of operation.

Postmortem examination was made September 18, 1924. The body was that of an emaciated young adult male. Slight jaundice was noted. There was a healed surgical scar 6 inches long, from navel to pubis. The abdomen was free from fluid and signs of inflammation. There was a firm tumor mass in the retroperitoneal region extending from the third lumbar vertebra up to the liver, adherent to the liver and the right kidney, and displacing the pancreas forward. A segment of the upper jejunum or duodenum was closely adherent to the tumor and ran along the upper surface. The tumor mass was 15 centimeters long by 10 centimeters wide by 7 centimeters deep. It was firm, yellowish, without evidence of necrosis in the center. It enclosed several large arteries and the vena cava. The duodenal segment was sectioned and there was disclosed a large ulcerating excavated area, 7 centimeters by 10 centimeters, where the tumor had invaded the wall and fungated into the lumen. The vena cava passed near the base of this excavated area and here there was complete thrombosis of the vein, the thrombus running up and for 4 inches, where it had been cut through. A few small separate metastases were present in the mesentery. The liver showed rather numerous small metastases up to 2 centimeters in diameter. The lungs showed several pea sized metastases. There was no pneumonia. The bronchial node was nega-

tive. The right testis was about normal in size, but on section showed opaque tumor tissue invading about one half of the gland area and all the rete. The epididymis appeared to be involved by rather firm tumor tissue without enlargement. The tumor mass was yellowish and apparently much fibrosed. The left testis was normal.

The anatomical diagnosis was carcinoma of the testis, metastases to the retroperitoneal region, liver, and lungs, ulceration of tumor mass fungating into duodenum. There was thrombosis of the vena cava.

Microscopical examination of sections showed an embryonal adenocarcinoma becoming diffuse carcinoma in the primary and all secondary tumors. There was very marked necrosis of the tumor in all lesions. The cells were very large, polyhedral and elongated, with clear or vacuolated cytoplasm and very hyperchromatic nuclei.

CASE 3. L. H., aged 27 years, was first seen at the Memorial Hospital on December 5, 1931, with the following history. The right testicle was removed 12 years previously for "blood tumor" which had been present for 3 months. He now complains of pain in the abdomen and back, nausea and vomiting, loss of weight and appetite. No gynecomastia present. The Aschheim-Zondek test was positive.

Postmortem examination, January 11, 1932, revealed no right testis. There was no sign of local tumor. Both lungs filled the chest cavity, were grayish, moderately emphysematous, and were riddled with miliary metastases throughout. These formed large confluent masses in the right lower lobe. The hilum nodes were greatly enlarged and were

Fig. 5. Case 9. C.G. Diagnosis: choriocarcinoma. Autopsy findings: Pulmonary foci, cns synges occluded, bronchial nodes, neoplasms in right uricle, neoplasms in inferior vena cava, retroperitoneal mass around left kidney, spermatic vein occluded, retroperitoneal disease extending to base of heart, inguinal nodes.

replaced by tumor which had secondarily invaded the trachea and primary bronchi to the bifurcation. This tumor was very soft, broken down, and may well have been the source of the interstitial emphysema. The node masses compressed the bronchi and vessels. The former yielded considerable thick mucopurulent material when sectioned. The stomach was pressed downward by an enlarged liver and metastatic deposits in the lesser omentum. The intestines, aside from downward displacement, were normal. The retroperitoneal nodes were completely replaced by tumor from the sacral promontory to the lung hilum and were continuous with those of the upper mediastinum. The kidneys were normal. The right ureter was normal. The left ureter showed an area of tumor metastasis which involved both the serous covering and the lumen. The left testis grossly was normal.

The anatomical diagnosis was embryonal carcinoma of the testis, generalized carcinosarcoma in invasion of the trachea and bronchi by metastatic node deposits with interstitial emphysema.

Microscopic examination showed diffuse embryonal carcinoma. Section of the thyroid showed cystic dilatation and colloid retention, of the testis marked diffuse hyperplasia of the cells of Leydig.

CASE 9. T.C., aged 46 years, was first seen at the Memorial Hospital on December 6, 1932, with the following history: He first noticed a mass in the left testicle and left kidney region on September 5, 1932. He had had back pain in the left upper quadrant for about a year previously. The testicle had been

Fig. 6. Case 14. C.S. Diagnosis: Primary choriocarcinoma. Autopsy findings: brain metastases, pulmonary disease, anterior mediastinal disease, liver disease.

removed September 28, 1932, with a diagnosis of embryonal teratoma. When patient was first seen there was a mass in the upper part of left inguinal canal which extended into the abdomen (laying of the cord?). There was no history of trauma or of gynecomastia. The Aschheim-Zondek test showed positive high prolan. Patient was jaundiced at postmortem examination, which was made June 7, 1933. The left testis was not present the right was trophied. There was thickening and brownish of the skin over the left abdomen (ray). Both lungs showed multiple red, hemorrhagic nodules over the surfaces. These were soft and bulging on section, representing hemorrhage with metastases which looked like chorionic metastases. There were 6 to 8 nodules of 5 centimeters, in the left lung and in the right. There was noted slight emphysema of the right lung with congestion of both bases, especially that of the left lung. The bronchial nodes were not involved. The liver was slightly enlarged, reddish-brown, with multiple raised reddish nodular masses over the surface. On section these measured to 5 centimeters and were soft and hemorrhagic, again suggestive of chorionic metastases. The left kidney had a large amount of fat adherent to the capsule. There was a large irregular, hard mass at the pelvis and lower pole. On section hydronephrosis with the ureter buried in hard irregular mass about 8 centimeters in diameter was noted. This mass was white in areas but was generally replaced with hemorrhagic soft tissue. From this lower region of the kidney pelvis the nodes on the left side were enlarged and hemorrhagic down to the left iliac region. The kidney was of a light green color. The right kidney was enlarged and

swollen and showed moderate jaundice. The abdominal lymph glands, described on the left retroperitoneal side up to the kidney, were hard, nodular, and hemorrhagic. On the right there was no enlargement. The lower pelvis, about the prostate and bladder was fibrosed and densely adherent to the posterior lateral walls. The left testis was absent, the right atrophic.

The anatomical diagnosis was metastatic embryonal carcinoma involving the abdominal lymph nodes, liver, and lungs, hydronephrosis, cholelithiasis, atrophy of the testis, right, and absence of left, jaundice.

Microscopical examination showed diffuse embryonal carcinoma with necrosis and hemorrhage, adenocarcinoma, atrophy of opposite testis with interstitial cell hyperplasia.

CASE 10. C. G., aged 37 years, was first seen at Bellevue Hospital, on February 5, 1919, with the following history. In October, 1918, patient had sudden pain in the right iliac region. The local medical doctor prescribed a cathartic and the pain disappeared but patient felt as if there was something obstructing the bowel in that region. He did not vomit. Soon after he started having cough, night sweats, evening rise of temperature, fatigue, loss of weight—30 pounds in 3 months. He gave no history of trauma, no history of gynecomastia. No Aschheim-Zondek test was made. The epididymis was enlarged and tender on the right.

Postmortem examination was made April 7, 1919, and showed the following. The chest was opened and two egg sized firm globular masses came into view in the region of the upper precordial area. The right side of the heart was opened and a large quantity of firm, raspberry colored clot escaped. Both lungs were large and heavy. Nodules were present and measured from 1 to 6 centimeters in diameter. These projected above the cut surface. They were friable, finely granular, contained innumerable and irregular outlined reddish specks which corresponded to hemorrhage. Others were reduced to soft, pultaceous masses. The peribronchial nodes were extensively infiltrated and the aorta was embedded in similar tissue. Practically the whole lower lobe of the right side was replaced by neoplasm. The left kidney was embedded in nodular tissue material. No intrinsic neoplasm was found on gross examination in either kidney or suprarenal gland. The right testicle tunica vaginalis contained considerable thin, straw colored fluid. The testicle was increased to the size of a hen's egg. On section, the upper extremity presented an irregularly outlined, firm, whitish, almost pearly, elevated tumor, scattered through the substance of which were moderate numbers of reddish specks. Just below this the testicle presented a large pultaceous, partly granular infiltrating growth which was dark cream colored. Living to the side of this tumor, the epididymis was visible as a bean sized yellowish, finely angulated body. The spermatic cord was markedly thickened and infiltrated by tumor tissue. On section, the spermatic

vein was found to be the size of the little finger and was filled with a grayish red, attached clot. The retroperitoneal tissues were involved from the left external iliac vein to the base of the heart. The vena azygos was enlarged and filled with tumor tissue. When the liver was removed it was found that the vena cava was almost completely occluded by reddish, raspberry clot. The intima was thickened and attached to it was a quantity of finely granular, reddish, tumorous material. The left femoral vein was thrombosed with tumor tissue. The inguinal nodes on the left side were enlarged and faintly cream colored. The liver contained no gross metastasis.

The anatomical diagnosis was chorionepithelioma of the right testicle, extensive infiltration of the corresponding spermatic cord, with neoplastic thrombosis of the spermatic vein, extension of tumor clot into the auricle of the heart, massive pulmonary metastases, bilateral, extensive neoplastic infiltration of the perirenal connective tissues and of the tissues surrounding the aorta from commencement to bifurcation, neoplastic infiltration of tissues around the left common iliac artery and vein.

Microscopical examination confirmed the diagnosis of chorionepithelioma.

CASE 14. C. S., aged 15 years, was first seen at the Memorial Hospital May 24, 1935, with the following history. For past 2 months had noticed weakness, past 3 weeks, shortness of breath, pain in right shoulder and right side of chest. On May 10, 1935, roentgenograms of the chest had been made elsewhere and showed a large mediastinal mass. No cough or weight loss noted. Both testes were atrophic, about one-fourth normal size. There was no history of mumps. In view of the bulky intrathoracic metastatic tumor in a young man and in view of the atrophic testes, the Aschheim-Zondek test was suggested. It was made and showed a high prolactin content. There was no history of trauma and no gynecomastia.

Autopsy was performed June 24, 1935, and showed the following. The tissues of the anterior mediastinum were edematous. Overlying the entire anterior pericardium, attached thereto and to the diaphragm and fusing inseparably with the portion of the right lung overlying the pericardium was a bulky, soft, brownish, cystic hemorrhagic mass of tumor. It was too low for a typical thymoma and failed to surround the great vessels at the base of the heart. The heart itself was negative. Throughout the lung parenchyma were numerous similar tumor nodules. None communicated by ulceration with the dissected bronchi. Some appeared on the pleural surfaces and one was adherent with the parietal pleura over the ninth and tenth ribs on the right in the axillary line. The right visceral pleura showed gelatinous edema. Both testes were firm but small. In the left testis was a small, firm, elastic, whitish nodule about 4 millimeters in diameter,

separate from that was a somewhat smaller grayish mucoid looking nodule. The former looked like fibroma. The brain, scalp, and calvarium were negative. The meninges showed slight yellowish edema with xanthochromic fluid. No gross hemorrhage was present. A small hemorrhagic cortical metastasis about centimeter in diameter was noted in the right occipital lobe in the superior lateral portion. Hemorrhagic metastases 3 centimeters in diameter easily enucleable were noted in left cerebella hemisphere and were surrounded by pronounced yellowish gelatinous edema. No gross obstruction was noted in the fourth ventricle; the lateral ventricles showed decided dilatation. The source of a spinal hemorrhage must have been

located low down. The pituitary gland was normal on gross inspection.

The anatomical diagnosis was chorionoma of left testis, fibroma of left testis, testicular trophoblastic tumor, primary mediastinal teratoma, (?) embryonal carcinoma of lung, metastases to lung, liver, brain, cerebellar edema, congestion of liver, spleen, and kidneys.

The microscopical examination revealed teratoma testis, primary consists only of adult mucous glands and cholesteatomatous cyst with no ascertainable malignant local residue; metastatic chorionepithelioma—in gross mediastinum, liver, brain, testicular trophoblastic and extreme interstitial cell hypertrophy and hyperplasia.

ARTHROGRAMS OF HIP JOINTS OF CHILDREN

Dr ERIK SEVERIN, Stockholm, Sweden

IN the investigations now being carried out at the orthopedic clinic in Stockholm on the many unsolved problems concerning congenital dislocation of the hip, the arthrographical study of such hip joints has proved extremely useful. Because of its cartilaginous nature, a great part of the hip joint of a child is outside the scope of roentgen-anatomical studies, unless a contrast medium is used.

The literature on hip joint arthrography is scarce. Some authors have contented themselves with determining the shape and size of the caput from the arthrogram, in cases of congenital dislocation of the hip, the breadth of the isthmus has been ascertained together with the presence of ligamentum teres, etc. In his book *Untersuchungen ueber die Aetiology und Pathogenese der angeborenen Huftverrenkung*, however, Faber has given a clear description of how the free border of the cartilaginous acetabulum can be identified. He also points out how this identification provides further means of distinguishing between a normal hip and those in different stages of caput displacement: if the joint is to be styled normal, the border of the cartilaginous acetabulum should reach down laterally to the horizontal line through the Y-shaped cartilages or in its immediate vicinity, if this border is displaced upward a subluxation has developed, and when the caput has come away completely from the acetabulum, a complete dislocation results.

No one, however, has paid much attention to the details in the medial part of the arthrogram. In the hope of confirming the correctness of earlier arthrogram findings and also to add to our knowledge of the details found in arthrograms of the hips of normal children, we have carried out an investigation which is here discussed.

The material used consisted of arthrograms made at the Clinic and also of specimens of

hip joints from stillborn children at full term.

A mixture consisting of cinnabar and celloidin—film being dissolved in acetone—was injected into the hip joints of the postmortem specimens. For the sake of simplicity, this mixture will be called "cinnoidin."

As cinnoidin flows sluggishly, the injection was carried out by means of a metal syringe. The threadworm of the pistonshaft was passed through the nut at the end of the syringe so that the piston could be screwed forward with some force. The joint was punctured from the front, and a few small stitches were placed around the point of the syringe with silk. During the process of injection, the distention of the joint capsule was checked by the fingertip, to ensure that it was complete but not excessive. By the careful moving of the joint, the cinnoidin was distributed within it. The preparation was placed in a diluted formalin solution for some weeks to prevent it from drying. When the cinnoidin had solidified, and this could be determined by pricking with a needle, the arthrographic cast was checked by roentgenogram and subsequently dissected for comparison with the roentgen pictures. The bright red color of the "fixed" arthrogram facilitated dissection.

Complete agreement cannot be expected between the cinnoidin-arthrograms and those arthrograms made with perabrodil in clinical patients. Compared with perabrodil, cinnoidin flows slowly, and a good deal of the soft parts had been removed during dissection of the postmortem material. This should be taken into consideration in passing judgment.

Comparison of the clinical arthrograms with the cinnoidin preparations and their roentgenograms reveals the following:

At the insertion of the synovial membrane on the femoral neck, the contrast medium is collected into a ribbon round the neck (Fig 1, A).

The orbicular zone, B, appears as a circular attenuation in the contrast material, medial to the neck ribbon. The synovial membrane

From the Carolina Institute's Orthopedic Clinic, Vanföresanstalten, Stockholm, Professor Henning Waldenström, Director.

Fig. Arthrograms of hip joint (schematic drawing). *A*, ligaments round the femoral neck, *B*, orbicular zone, *C*, fibrocartilaginous limbus, *D*, capsule pocket outside transverse ligament, *E*, impression of transverse ligament, *F*, recessus fossae acetabuli.

bulges out again above the orbicular zone and makes room for larger quantities of contrast material between itself and the caput, the shape and size of which is beautifully reproduced in the arthrogram.

In the upper parts of the joint, the fibrocartilaginous limbus, *C* protrudes into the contrast medium like a ploughshare. The recess situated outside the limbus is filled with contrast material up to the synovial mem-

Fig 3 Arthrograms of the right hips of two stillborn children, taken with cannoidin. A, ribbon round the femoral neck, B, impression by zona orbicularis, C, impression by fibrocartilaginous limbus, D, capsule pocket outside transverse ligament, E, impression of transverse ligament, F, recessus fossae acetabuli (F_1 , ventral, F_2 , dorsal)

brane root some millimeters from the free limbus edge. The limbus thorn affords a sure base for the extent of the acetabulum upward. Beginning on the inside of the limbus, there is the space of the joint which *in vivo* normally has a thinner contrast material content than is to be obtained in the postmortem material.

Normally, then, the quantity of contrast medium between the femoral head and the acetabulum is very small, except medially. Here the contrast material is collected partly in the fossa acetabuli—i.e. medial, F , to the ligamentum transversum, E —partly in the relatively generous capsule pocket, D , which is to be found immediately outside the liga-

mentum transversum, E . The pointed fibrocartilaginous limbus merges into the ligamentum transversum at the incisura acetabuli.

Fig 4 Preparation of the arthrogram seen in Figure 3b, seen from the medial, a, and ventral, b, sides. C, impression by fibrocartilaginous limbus, D, capsule pocket outside transverse ligament, E, impression of transverse ligament, F_1 , recessus ventralis fossae acetabuli, F_2 , recessus dorsalis fossae acetabuli.

Fig 5 Arthrogram of a child's normal hip joint. Perabrodil was used. A, Ribbon round the femoral neck, B, impression by orbicular zone, C, impression by fibrocartilaginous limbus, D, capsule of pocket outside the transverse ligament, E, impression of transverse ligament, F_{1-2} , recessus ventralis et dorsalis fossae acetabuli.

Sectionally the ligamentum transversum is rounded and on account of its extension mainly in a dorsoventral direction seems, in pictures taken in a dorsoventral plane to appear in the contrast medium as a rounded impression (*impressio ligamenti transversi*) *E*.

According to Faber the quantity of contrast material in the bottom of the acetabulum is, normally extremely slight, but according to our investigations one should take into account the normal variations brought about by varying injection pressures, decreased muscle tonus under a narcotic, incongruity between the caput and acetabulum or the like. Naturally the quantity of contrast material contained in the fossa acetabuli also influences the size of the contrast medium pool in the bottom of the acetabulum.

The quantity of contrast medium which lies in the fossa acetabuli and which forces its way down medial to the ligamentum transversum, is parted at its lower tip into two prongs—a ventromedial, *F* and a dorsolateral, *F*₂, the anatomical foundation of which are the two pouches, which the author names *recessus ventralis fossae acetabuli* and *recessus dorsalis fossae acetabuli*. The site of origin of the ligamentum teres, *H* from the medial side of the ligamentum transversum is joined to the bottom of the fossa acetabuli with a few firm tissues. If the contrast medium is subjected to pressure from above the soft parts in the fossa cannot recede uniformly but bulge into two pouches, whose divisional wall is supported by the aforementioned tissues between the bot-

tom of the incisura and site of origin of the ligamentum teres. Thus, both the resultant contrast prongs are usually projected onto one another but if they appear in the arthrogram it is possible, with their help, to point exactly to the spot where we should look for the origin of the ligamentum teres.

In cases of congenital dislocation of the hip, one or more of the arthrographic details noted may be distorted or obliterated through more or less extreme secondary changes.

SUMMARY

Casts, obtained by dissection after being photographed and compared with corresponding roentgen pictures, have helped to show where contrast medium is collected in arthrography of hip joints of normal children. The details of the arthrograms have been directly identified in the specimens. Comparisons have also been made with clinical arthrograms.

The extent of the cartilaginous acetabulum may be determined laterally with the aid of the limbus thorn, medially with the aid of the ligamentum transversum which at a suitable projection, appears in the contrast medium as a rounded impression (*impressio ligamenti transversi*). Time and again one sees the quantity of contrast medium situated medial to the ligamentum transversum, parted into two prongs by the origin of the ligamentum teres. These two prongs are enclosed in two pouches which the author names *recessus ventralis fossae acetabuli* and *recessus dorsalis fossae acetabuli*.

THE IMPLANTATION OF SOLID PELLETS OF ESTROGENS IN THE TREATMENT OF MENOPAUSAL SYMPTOMS

GRAY H TWOMBLY, M D, and ROBERT S MILLEN, M D, New York, New York

IT is the purpose of this paper to report the use of solid pellets of estrogenic materials in the treatment of 37 patients suffering from menopausal symptoms. Four patients with kraurosis and leucoplacia of the vulva have been similarly treated. In addition, pellets have been given to 4 patients with leucoplacia buccalis or chronic stomatitis, following out the work of Nathanson, who has treated successfully patients with leucoplacia by repeated injections of estrogens in oil. A single case of what appeared to be hyperfunction of the adrenal cortex was treated. In general, those suffering from menopausal symptoms have been greatly relieved by the pellets for periods varying from 5 months to more than a year. The patients with kraurosis have been somewhat improved but not cured. No effect has been noted on leucoplacia buccalis or chronic stomatitis. The only noticeable effects on the hirsute woman was the suppression of her scanty menstrual periods for 2 months.

In 1937 Deanesly and Parkes published their observations on the prolongation of estrogenic effects in capons by the implantation of solid crystals of estrone beneath the skin. Whereas 4 milligrams of estrone dissolved in sesame oil and injected subcutaneously into a brown leghorn capon caused the appearance of a narrow brown stripe on the growing black breast feathers of the bird, a smaller amount (3 mgm) implanted as a crystal beneath the skin resulted in a total change in color of the growing feathers to brown and this effect was continued for nearly 3 months. Similar prolongation of hormone effects was shown in castrated rats by the implantation of testosterone pellets.

The fundamental idea of using the almost insoluble steroid hormones in solid pellet form to obtain long continued hormonal effects has

been used subsequently by many investigators, with excellent results. Thorn's (11, 12) experiments using desoxy-corticosterone in cases of Addison's disease are well known. Howard and Vest and Hamilton have used pellets of testosterone propionate to good effect. More recently Hartman has reported a careful series of experiments on monkeys in which he used pellets of estrogens, progesterone, and testosterone. He records effects from a single 3 milligram pellet of theelin lasting for 4 months or longer.

Fig 1 Endometrium from a woman treated with two 15 milligram pellets of α -estradiol showing the typical Swiss-cheese type of endometrial hyperplasia produced by hyperestrinism. The patient had had a spontaneous menopause 4 months before pellet implantation. Biopsy taken 7 months after therapy, 4 months after bleeding started.

Fig. 2 Vaginal smear from girl of 20 who had been castrated by x-ray therapy for dysgerminoma of the ovary. Note the predominance of deep cells and the absence of any large cornified epithelial cells with pyknotic nuclei.

Fig. 3 Completely cornified smear from the preceding patient one month after implantation of 20 milligram pellet of estradiol.

Estrogens have been used in solid form to obtain very prolonged effects by Twombly who produced cancer in male mice of a susceptible strain (R III) with a single crystal of estrone given at 10 days of age and by Geschickter who produced mammary cancers in rats similarly treated. Bishop used a 14 milligram pellet of estrone in a patient suffering from menopausal symptoms and reported a reduction in the number of flushes from 10 to 12 a day to 4 to 6 a day, the effect lasting about 7 weeks. Salmon, Walter and Geist using crystals of α -estradiol benzoate implanted 10 menopausal patients with 4 to 7 milligrams each and reported marked improvement in symptoms lasting from 60 to 98 days.

The experiments of Deaneley and Parkes seemed so striking that their application to women with menopausal symptoms immediately suggested itself and was begun on a

cautious scale in the fall of 1937 in our own clinic. Crystalline estrone was dissolved in ethyl alcohol and recrystallized, the crystals so obtained weighing from 1 to 14 milligrams. These were sterilized by boiling and introduced into the gluteal muscles by insertion through a small trocar. Later at the suggestion of Professor Parkes, pellets of estrone weighing 15 to 30 milligrams were used while all the recent cases have been treated with one or more 20 milligram pellets of α -estradiol.¹

These last pellets are firm and smooth, measure 3 by 2 millimeters, and are supplied sterile in glass ampuls. They are boiled for 3 to 5 minutes after removal from the tube as an extra check on their sterility and are inserted through a trocar size 10 French, such as is supplied by surgical supply houses for

¹The crystalline estrone was obtained from the Schering Corporation through the kindness of Dr. Ervin Schering. The estrone pellets and the pellets of α -estradiol were supplied by Dr. N. Macklin of the A. V. Organon Company, London, and by Dr. R. D. Spenser of Radio-Organon, Inc., Nutley, N. J. These men are well known for their proficiency.

tapping hydroceles The material has been inserted intramuscularly into the buttock through a novocain wheal, no incision or suturing being necessary The resultant scar is negligible

The first patients were treated with crystals of estrone alone Of these there were 4 There were 13 women who had crystals or pellets of pure estrone inserted first, followed at a later date with pellets of estradiol Fourteen patients had treatment either before or after pellet implantation with diethyl-stilbestrol given as tablets by mouth (1 to 2 mgm daily) or intramuscularly three times a week in doses of 0.2, 1.0, or 2.0 milligrams in oil A number of patients had previously had treatment with intramuscular injections of estrone in oil¹ before receiving pellets Finally there were 42 patients who received from 20 to 60 milligrams of α -estradiol each, 23 of whom had no other form of estrogenic therapy

In treating patients suffering from menopausal symptoms, it has been impressed repeatedly upon us that one is dealing not only with the physiological lack of hormone but also with a complicated psychic pattern—the result of the patient's age, economic and social background, changing marital relationships, etc The latter symptoms are often curable simply by the frequent sympathetic questioning of the patient by the physician This is particularly true of the patients in the age group between 40 and 55 Some, in contrast, are very resistant to treatment of any kind, but in such cases we have found several times on questioning the patient carefully that clinical cure would entail the necessity of her going back to work or perhaps might result in a cut in home relief or in some way might be disadvantageous

Because it is so hard to get a reliable idea as to the degree of benefit from any form of therapy in these women, we have made it a rule to treat only patients with severe symptoms who were willing to count the number of flushes they had daily The effort required in this procedure eliminates many patients with mild symptoms and makes the results of therapy somewhat more objective Most of the patients have been followed from week to week

¹Theclol-Parke Davis Company

Fig 4 Record of hot flushes in the same patient showing complete disappearance in 1 month with a gradual return to the pretreatment frequency in 5 months

with studies of the vaginal smear In addition, the condition of the cervix and breasts, and other menopausal symptoms such as headache, dizzy spells, insomnia, crying spells, etc, have been noted at each visit

To illustrate the difficulty of accurately estimating the effect of medication, the first case may be cited, in which 4.8 milligrams of estrone completely abolished all hot flushes for at least 6 months though there was no change in the atrophic menopausal vaginal smear A number of patients have been cured of their symptoms merely by being required to count their flushes

In the other direction, a patient treated with 50 milligrams of estradiol and 100 milligrams of diethyl-stilbestrol, given both by mouth and intramuscularly, never showed any striking relief of symptoms but rather a slow improvement This effect seems significant when one knows that she is a confirmed attendant in the out-patient department of half a dozen other clinics A second patient showing no benefit complained, after 60 milligrams of estradiol in 4 months, that she felt so poorly that she ought to be on home relief but that the authorities would not agree that she was sick enough to stop working Her vaginal smear showed a full estrogenic effect

The most satisfactory results of treatment have been obtained among young people who are surgical or radiation castrates Three of these, 20, 25, and 30 years of age, have all shown complete cure for 3 to 6 months from

1 or 2 pellets of estradiol. In addition to their prompt reaction to treatment, they have failed to show the other psychoneurotic manifestations so frequently seen in the older patients.

Of the total of 46 patients treated, 17 were suffering from menopausal symptoms following surgical castration or hysterectomy. 14 had been treated with radium or roentgen rays while in 12 the symptoms followed a spontaneous menopause. Three patients were still menstruating. In general, the women who had been surgically castrated were more refractory to treatment than either of the other groups. They required from 1 to 3 pellets for complete relief of their symptoms, the average dose being 2; these usually being given within a month of each other. Those treated previously with radium were more easily relieved. They received only 1 pellet in 8 cases, 2 in 5 and 3 in 1; the average dose being $1\frac{1}{4}$. The 12 women who were suffering from post-menopausal symptoms after a spontaneous menopause were all treated with only 1 pellet, save in 2 cases, both suffering from kraurosis vulvae. The first of these was given two 20 milligram pellets a month apart, and the second 3 pellets. Of these 12 patients, 9 had uterine bleeding, starting 1 to 3 months after treatment, lasting from a few days to a year. This was severe enough in 1 case to require curettage and radium. Another should have been treated in the same way but refused. Three patients treated recently have had no bleeding. One of the surgical castrates bled 7 weeks after pellet insertion evidently from part of the lower portion of the uterus which had not been removed at the hysterectomy 2 months before treatment.

Women who have had a spontaneous menopause are relieved of their symptoms much more easily than surgical or radiation castrates, and this is what one would expect, since the ovary still has some activity even after the menstrual periods have ceased. However, the uterine bleeding, which has occurred in three-quarters of these cases, would seem to contra-indicate treatment by pellets. In 5 of the patients who bled for a considerable length of time it was possible to obtain pieces of endometrium for study in 1 case by formal curettage under a general anesthetic, and in

the others by the use of a suction curette. All 4 patients showed the typical Swiss-cheese pattern of the endometrial glands typical of prolonged estrogenic stimulation. The microscopic section of one of these specimens is illustrated in Figure 1.

The pellet form of therapy has been very satisfactory in the patients treated with estradiol. All but one of the menopausal women have shown moderate to marked improvement or complete cessation of symptoms. This improvement has included abolition of hot flushes, improvement in sleep, great improvement in nervousness, cessation of crying spells, relief of headaches, and the advent of a feeling of well-being. The effect from a single implantation appears to last a variable length of time. Those patients in whom the effects seemed the most objective had relief for 5 to 6 months. In others relief lasted longer. It is our impression that the effect of estradiol in pellet form is more marked than anything we have been able to obtain with diethyl-stilbestrol or estrone in oil. Because of the expense of the latter drug for clinic patients, it may be that we have not administered it in large enough doses over long enough periods, but several patients, later treated satisfactorily with pellets, have had as much as 10,000 international units of estrone in oil 3 times a week for 3 weeks or longer. Diethyl-stilbestrol in our hands has given a high percentage of toxic effects. 6 of the 12 patients complained of nausea or abdominal pain when taking the drug by mouth. These symptoms have occurred occasionally even when the material was given by hypodermic injection.

In our hands the implantation of solid pellets of estrone have been practically without effect. One patient received four 15 milligram tablets at one time, another two 30 milligram tablets, another 65.4 milligrams as one 30 milligram pellet and about ten crystals, all without benefit.

As has been described by Papanicolaou and Shorr, the human vagina undergoes atrophy following the menopause with a marked thinning of the cornified layers of the epithelium. This thinning is accompanied by the appearance in the stained vaginal smear of leucocytes and large round cells with large nuclei, deep

cells" as they are called by these authors. These cells form the deeper or basal layers of the mucosa. In some cases the entire smear may consist almost entirely of them. In other cases, though the epithelial cells are large and polyhedral, the nuclei are quite large and palely staining. Under the influence of adequate amounts of ovarian hormone, the leucocytes tend to be greatly reduced in number or to disappear altogether, while the "deep cells" disappear completely. The epithelial cells become large and flat, and their nuclei shrink so that they are small, pycnotic, and deeply staining.

We have studied the vaginal smears in 35 of our cases and classified them as 0 to ++++, depending on the degree of cornification that they show. By 0 we mean a smear composed of small round cells with relatively large nuclei. Leucocytes may be present in abundance. Of the 26 cases in which smears were taken before therapy was begun, 11 showed this picture, one type of which is illustrated in Figure 2. When the smear contained only a few of these cells it was spoken of as +. Four pretreatment smears were thus classified. If the smear showed large polygonal epithelial cells with large pale nuclei and many leucocytes, it was labeled ++. There were 5 of these in the pretreatment smears. If there were few leucocytes and most of the epithelial cells showed pycnotic nuclei with less than half of them showing large nuclei, the smear was labeled +++. There were 6 of these. By ++++ we mean a smear consisting of large polygonal cells all of whose nuclei are small and heavily stained. Either no leucocytes or only a few are present (Fig. 3). This type of smear was not found in untreated cases.

In 24 of 30 patients treated with estradiol pellets in whom smears were taken after treatment, complete cornification was seen. Three patients showed smears classified as ++++. In 3 cases menopausal smears were found after treatment. The explanation for the failure of these patients to show a response in the vaginal smear is difficult. One patient certainly had a physiological response from the drug, for her breasts enlarged and the uterus increased in size. A second patient who had received 40 milligrams had complete relief

of hot flushes but continued to show deep cells in the smear. The third suffered from kraurosis. It has been our experience that patients with kraurosis require large doses to give any physiological response, and the fact that this woman failed to show any smear changes with one 20 milligram pellet corresponds with this clinical observation.

Several effects other than those it was desired to produce, in addition to the uterine bleeding already mentioned, deserve description. These include swelling and soreness of the breasts of mild to moderate degree lasting for a few days to a month. This occurred in about half of the patients. In 4 cases leucoplacia of the cervix was seen to develop following therapy. Biopsies in all of these cases showed only thickening of the epithelium without downgrowth into the underlying muscle. One patient who bled for almost a year after treatment developed a cervical polyp first, about 2 months after insertion of the estradiol. This was also true of the last case. Two patients complained of severe headaches for about a month at the time when it was judged that the effect of the pellet was wearing off. One patient with multiple fibromyomas of the uterus showed a definite increase in size of these tumors. The uterus before treatment was described as being about the size of a 2 months' gestation, whereas a month later it reached almost to the umbilicus. The same was true of a second patient though the growth was not quite so marked.

Finally, this report would not be complete without a word on the relationship of this form of therapy to cancer of the breast. As has been mentioned, cancer can be produced in male mice with single implantations of crystalline estrone. In the patients we are reporting, as much as 720,000 rat units of estradiol have been given to 1 patient. Because such an amount of drug might be thought dangerous, especial care has been taken to follow our cases, particularly with regard to the condition of the breasts and cervixes. In no case as yet has any mass developed in the breast. The only lesions of the cervix have been described. In this respect our experience agrees with that of Shorr and Papanicolaou (10) who report 452 patients treated from 1 to over 7

years with doses of 50,000 to 3,000,000 rat units of estrogenic material without a single case of cancer which could be attributed to the therapy they had received.

In our series there were 2 patients who had been treated with radium one 5 years and the other 7 years previously for carcinoma of the cervix. One girl of 20 had been treated for very extensive metastatic dysgerminoma of the ovary by x rays one year before estradiol therapy. None of these 3 patients has shown any evidence of reactivation of the tumor by the drug.

SUMMARY

1 Thirty seven menopausal patients, 4 cases of kraurosis vulvae 4 cases of leucoplacia buccalis and 1 case of adrenogenital hirsutism have been treated by the implantation of solid crystals or pellets of estrone or estradiol.

2 Estrone crystals and pellets have been ineffective in our hands.

3 Twenty-milligram pellets of estradiol have proved most efficacious for the prolonged alleviation of menopausal symptoms. The effective dose has been a total of 1 to 3 pellets given intramuscularly a month apart.

4 The full effect of the pellets becomes apparent in about 1 month. The effect lasts 5 months to a year as shown by subjective symptoms and vaginal smears.

5 Pellets are contra indicated in women with intact uteri, since they have caused bleeding (quite profuse and prolonged in some cases) in 9 of 12 such patients treated. No bleeding has occurred in patients who have received castrating doses of radium some time before estrogenic therapy.

6 Pellet therapy was only partially effective in 4 cases of kraurosis vulvae.

7 A woman with marked hirsutism had her menstrual periods inhibited for 2 months but

no improvement in the excessive hair growth was noted.

8. No case of carcinoma of the breast or cervix has been produced. Two cases of carcinoma of the cervix and one of dysgerminoma of the ovary have shown no reactivation of the disease by this form of medication.

CARCINOMA OF THE LOWER INTESTINAL TRACT

ROLAND E. BIEREN, M D, Baltimore, Maryland

IN the interval between January, 1922, and June, 1939, there have been 254 cases of carcinoma of the large bowel (including 2 of the appendix and 10 of the anus) in the University Hospital.¹ It was felt that a systematic study of the material presented by these cases would be of considerable clinical and pathological interest and would be representative of an average general hospital. Such a study is here presented with a satisfactory follow-up of approximately 97 per cent of the cases. We are greatly indebted to many busy practitioners and to the departments of vital statistics of the Baltimore City and State of Maryland health departments for invaluable assistance in following these patients.

APPENDIX

There are 2 cases of adenocarcinoma of the appendix. Both occurred in white females, ages 44 and 49, respectively. Both presented the clinical picture of acute appendicitis. At operation the appendix was described as being gangrenous with abscess formation. The diagnosis of adenocarcinoma was made by the pathologist. One patient died in 3 days of peritonitis, the other survived operation to die in 2 years of generalized metastases.

COLON AND RECTUM

There are 242 cases of adenocarcinoma of the colon and rectum. For purposes of convenience they are divided into 3 groups: those occurring in the right colon, the left colon, and the rectosigmoid and rectum. Of the 40 cases of adenocarcinoma in the right colon, 24 involved the cecum, 9 the ascending colon, 7 the hepatic flexure. Of the 63 cases in the left colon, 9 involved the transverse colon, 5 the splenic flexure, 9 the descending colon, and 40 the sigmoid colon. The rectosigmoid and rectum were involved in 139 cases.

From the Department of Pathology, School of Medicine, University of Maryland.

¹Several inoperable cases were not proved by biopsy but were included in the study because the gross description at operation and the subsequent course justified the diagnosis of carcinoma.

Age. The highest incidence is undoubtedly in the age group 50 to 70 years, but youth is by no means ruled out, for 3 cases occurred in the age group between 17 and 19, 6 between 20 and 29, 14 between 30 and 39, 39 between 40 and 49, 76 between 50 and 59, 77 between 60 and 69, 26 between 70 and 79, and 1 between 80 and 89.

Race and sex. Of the patients with adenocarcinoma of the right colon, 29 were males, 11 females, 37 were of the white race, 3 of the black. Of those in whom adenocarcinoma occurred in the left colon, 35 were males, 28 females, 58 were white, 4 black, 1 yellow. Of those with adenocarcinoma in the rectosigmoid and rectum, 89 were males, 50 females, 133 were white and 6 black.

TABLE I — CHIEF PRESENTING SYMPTOMS

Symptom	Right colon	Left colon	Rectosigmoid and rectum
Constipation and/or diarrhea	13	41	89
Blood and/or mucus in stool	7	20	79
Abdominal pain	29	25	16
Palpable mass	16	13	5
Obstruction	12	11	18
Loss of weight	0	3	4
Anemia	8	1	0
Gaseous distention	0	5	0
Small stools	0	1	4
Rectal discomfort	0	0	26
Hemorrhoids	0	0	12
Urgency	0	0	7
Incontinence	0	0	4

Symptomatology. The chief presenting symptoms are given in Table I.

It was questioned whether there might be any relation between the duration of symptoms and operability. The average duration of symptoms of the adenocarcinomas occurring in the right colon in the entire group of patients was 10 months, in the operable group 5.5 months, in the inoperable group 11.7 months. The average duration of those occurring in the left colon in the entire group was 9 months, in the operable group 7 months, in the inoperable 10.5 months. The average duration was 10 months for those occurring in the rectosigmoid and rectum in the entire group.

years with doses of 50,000 to 3,000,000 rat units of estrogenic material without a single case of cancer which could be attributed to the therapy they had received.

In our series there were 2 patients who had been treated with radium one 5 years and the other 7 years previously for carcinoma of the cervix. One girl of 20 had been treated for very extensive metastatic dysgerminoma of the ovary by x rays one year before estradiol therapy. None of these 3 patients has shown any evidence of reactivation of the tumor by the drug.

SUMMARY

1. Thirty-seven menopausal patients, 4 cases of kraurosis vulvae, 4 cases of leucoplasia buccalis, and 1 case of adrenogenital hirsutism have been treated by the implantation of solid crystals or pellets of estrone or estradiol.

2. Estrone crystals and pellets have been ineffective in our hands.

3. Twenty milligram pellets of estradiol have proved most efficacious for the prolonged alleviation of menopausal symptoms. The effective dose has been a total of 1 to 3 pellets given intramuscularly a month apart.

4. The full effect of the pellets becomes apparent in about 1 month. The effect lasts 5 months to a year as shown by subjective symptoms and vaginal smears.

5. Pellets are contra-indicated in women with intact uteri since they have caused bleeding (quite profuse and prolonged in some cases) in 9 of 12 such patients treated. No bleeding has occurred in patients who have received castrating doses of radium some time before estrogenic therapy.

6. Pellet therapy was only partially effective in 4 cases of kraurosis vulvae.

7. A woman with marked hirsutism had her menstrual periods inhibited for 2 months but

no improvement in the excessive hair growth was noted.

8. No case of carcinoma of the breast or cervix has been produced. Two cases of carcinoma of the cervix and one of dysgerminoma of the ovary have shown no reactivation of the disease by this form of medication.

20 per cent, systemic disease in 6, or 20 per cent

Of 18 patients dying of peritonitis 7 came to autopsy. Four of these had leakage at the operative site, 3 were apparently due to contamination at operation.

It was questioned whether peritoneal drainage played any part in the prevention of peritonitis. In 37 of the 79 cases resected peritoneal drainage was employed. Eight of these patients died of peritonitis. Only 2 of these 8 came to autopsy, 1 was due to leakage and the other was not. We doubt that there is any significance in these figures.

TABLE III —MORTALITY BY ERA OF THE 17 YEAR PERIOD

Year	Resected	Deaths	Percentage
1922-1929	20	6	30
1930-1935	23	10	43
1936-1939	36	14	39

Operation	Number cases	Deaths	Per cent
One stage abdominoperineal resection	20	10	50
Two stage abdominoperineal resection	9	5	56
One stage resection with end to end anastomosis or ileocolostomy	30	11	37
Two stage resection (preliminary ceostomy) with end to end anastomosis	4	1	25
Mikulicz resection	4	2	50
Posterior resection, rectum	12	1	8

Prognosis of resected cases Of the 79 cases resected 49 patients survived the operation. All of the 49 have been followed satisfactorily to December, 1939, except 1, and that one was followed for 5 years and has been considered as a 5 year cure. The end-results are presented in Table V.

Thus 24 patients have survived 3 or more years, of these 3 have died of recurrence and 1 of cerebral hemorrhage. One patient has recurrence after a lapse of 15 years. We feel that this could be justifiably considered another tumor. Of the 25 remaining cases, 11 have died of carcinoma in less than 3 years, 2 have died of heart disease, and 1 of cerebral hemorrhage within the same period of time. Eleven patients are still living and well, having survived varying periods of less than 3 years, 2 of these with known liver metastases.

TABLE V —SURVIVAL, OPERATION AND GRADE OF TUMOR

Survival— years	Operation	Grade ¹	Present status
16	One stage abdominoperineal	4B	Living and well
15	Two stage abdominoperineal	2B	Recurrence after 15 years
14	One stage resection, cecum	1A	Living and well
13	Posterior resection	3A	Living and well
11½	One stage abdominoperineal	2A	Living and well
11	One stage transverse colon	3B	Living and well
10	One stage cecum	2B	Living and well
10	One stage sigmoid	3B	Living and well
7½	Posterior resection	2	Living and well
7	Mikulicz descending colon	2B	Colloid. Died of recurrence
6	One stage abdominoperineal	2B	Living and well
6	Two stage abdominoperineal	3B	Living and well
5½	One stage sigmoid	2B	Living and well
5	One stage cecum	3B	Followed only 5 years
5	One stage cecum	2B	Living and well
4½	One stage sigmoid	2B	Living and well
4	Mikulicz transverse colon	2B	Living and well
4	Posterior resection	3B	Died of recurrence
4	Posterior resection	?	Died of recurrence
4	One stage abdominoperineal	2	Living and well
3½	One stage abdominoperineal	2A	Living and well
3½	One stage abdominoperineal	3C	Living and well
3	One stage abdominoperineal	1A	Living and well
3	One stage abdominoperineal	3	Died of cerebral hemorrhage

¹Two methods of grading are employed. The one is the Broders method of grades I to IV; the other the Dukes method indicated by the letters A, B and C. We apply the Dukes method as follows: A indicates the growth is limited to the mucosa and submucosa; B indicates involvement of muscularis; and C indicates peritoneal or regional node involvement.

Survival by operative procedure Of those subjected to posterior resection, 11 survived operation, 2 died of recurrence after 4 years and 6 after 3 years or less. Two patients survived a Mikulicz resection and 1 is living and well 4 years later, the other died of recurrence after 7 years. In the group of one and two stage procedures, 37 patients survived operation. Only 5 have died of recurrence in 3 years or less.

We feel that recurrence after resection indicates one of two things: (1) that metastases already present were overlooked at the time of operation. This is shown by 2 of the patients who died after operation in whom were found previously unrecognized liver metastases at autopsy. (2) That the excision of the growth at the operation was insufficient. This is apparent in the high incidence of recurrence in the posterior type of resections.

Prognosis of inoperable cases Of the 163 inoperable cases 47 patients died while in the

as well as in the operable group and in the inoperable group.

The individual variance is from 24 hours to 5 years. The figures given in the previous paragraph appear significant. The difference in chronology between the groups is probably related to anatomical position and physiology of each portion of the bowel. Only 4 cases were discovered incidentally. One cecum, during laparotomy for acute cholecystitis; another descending colon, at autopsy on a patient who died of obstruction following hysterectomy; a third, sigmoid, at autopsy on a patient who clinically had a psychosis and symptoms of a brain tumor; cerebral metastases and the fourth rectum following cystostomy for acute urinary obstruction. Nineteen cases were diagnosed on admission of patients to hospital as having an acute abdomen. Of these 8 were due to perforation of the growth, 10 to the associated inflammatory reaction without perforation, and 1 was due to an acute cholecystitis.

Röntgenograms were made in 80 patients: 21 of the right colon of which 18 were reported as carcinoma, 2 inflammatory; 1 negative; 40 of the left colon, 34 of which were reported as carcinoma—case reported as carcinoma of the transverse colon but found at operation lesion in the descending colon—6 negative; 19 of the rectosigmoid and rectum, 18 reported as carcinoma, 1 negative. Of the total of 80 cases, 70 or 87.5 per cent were reported as carcinoma, 2 or 2.5 per cent as inflammatory and 8 or 10 per cent were negative.

One case was reported as carcinoma by roentgen ray and confirmed by laparotomy (but not by biopsy) which later proved to be diverticulitis. It is not included. In the 2 cases reported as inflammatory and in 7 of the 8 cases reported as negative the symptoms alone were still considered sufficient justification for laparotomy. Only 1 case reported as negative was missed entirely. This was the patient with a psychosis who was suspected of a brain tumor and in whom was found at autopsy carcinoma of the sigmoid with cerebral metastases.

Operability. Of the 242 cases, 79, or 33 per cent of the entire series, were operable; 11 or 27.5 per cent, of the 40 cases occurring in the right colon; 25 or 40 per cent, of the 63 in the left colon; 43 or 31 per cent, of the 139 in the rectosigmoid and rectum.

An operability of 33 per cent is low. This is partially explained by the criteria used for estimation of operability on the basis of metastases. There were 56 cases in which there were no demonstrable metastases but the local extent of the growth was the criterion for inoperability. There were metastases in regional nodes in 65 patients; in regional nodes and liver in 29 patients; there were regional and intra-abdominal metastases in 10 patients and generalized metastases in 3 patients.

There were 4 operable cases with metastases present in the regional nodes and liver. Two of these were missed at operation and were found at autopsy. The other 2 were recognized and the primary growth (rectum) was resected for relief of symptoms. Both are living and well, one 2 years and the other 1 year following operation.

TABLE II—TYPES OF OPERATION EMPLOYED

	Case
Right colon	
One stage resection	11th Ileocolostomy
One stage resection	11th Ileocolostomy and supplementary ileostomy
One stage resection	11th Bowstomy
Left colon	
One stage resection	11th end to end anastomosis
T stage resection	(preliminary cecostomy) 11th end-to-end anastomosis
One stage resection	11th end to end anastomosis and supplementary cecostomy
Mikulicz resection	
One stage abdominalperineal resection (sigmoid)	
Rectosigmoid and rectum	
One stage abdominalperineal resection	
T stage abdominalperineal resection	
T stage resection	11th end to-end anastomosis
Posterior resection	

Operative mortality. Of the 79 patients operated upon, there were 30 or 38 per cent, operative deaths; 5 or 45 per cent, of the 11 cases in the right colon; 10, 38 per cent, of the 25 in the left colon; 15, 35 per cent, of the 43 in the rectosigmoid and rectum.

Chief cause of death. Peritonitis—6 had obstruction—was the cause of death in 18, or 60 per cent, of the cases; operative shock in 6 or

¹The cases reported as negative have recently been reviewed by Dr. Walker L. Hulley of the Department of Pathology. In all of the cases was described but was considered inconclusive and the final impression was reported as being negative.

at Table V will confirm this for the Broders method The Dukes method appears significant, but it must be borne in mind that few cases in this series with peritoneal or regional node involvement were considered to be operable

Proper preparation of the patient has often been neglected Carcinoma of the colon and rectum is seldom, if ever, an acute surgical emergency Obstruction may well be one and at the same time should be a strong contra-indication to resection

THE CHOICE AND USE OF COTTON FOR SUTURE MATERIAL

S ARTHUR LOCALIO, M D, and J WILLIAM HINTON, M D, F A C S,
New York, New York

RECENT publications by Meade and Ochsner (8, 9) have focused attention on the use of cotton as a suture material In 600 B C Sushruta (2), the father of Hindu surgery, recommended the use of cotton sutures, and from time to time during the ages cotton has undoubtedly been used The earliest modern reference to the use of cotton is that of Ginkorski in 1936, who satisfactorily employed chemically sterilized cotton in 100 experimental animals and in 23 humans

The literature of the past decade has contained many articles (1, 4, 7, 10, 12) advocating the use of nonabsorbable suture materials Several objections have been raised to the use of catgut Among the more important of these are difficulty of sterilization, allergic sensitivity, variable absorbability, deleterious effects of chemicals, production of serum, delayed fibroblastic activity, and delayed wound healing Other criticisms are increased incidence of wound infection, dehiscence, postoperative herma, and unreliability of the square knot tied with catgut Silk presents none of these objections However, it has come into dispute with some surgeons because slowly healing sinuses occur if an infection develops

Meade and Ochsner attribute these to the presence of infected granulations in the silk itself These authors state that cotton shows less tendency for tissue ingrowth between its fibers, and hence is less likely to produce sinuses in the presence of infection Cotton, therefore, partially obviates the most serious objection to the use of nonabsorbable sutures

Meade and Ochsner further recommend cotton as an inexpensive, pliable, easily sterilized, suture material Due to its high coefficient of friction, cotton is not likely to slip after the first throw of a square knot Furthermore it can be tied with reliable square knots After it is implanted in a wound, catgut, silk, linen, and cotton decrease in tensile strength in the order mentioned Meade and Ochsner have graded suture materials with the following criteria in mind amount and persistence of leucocytic infiltration, amount of serum and fibrin, appearance time of fibroblasts, and the length of time necessary to produce final healing Wounds sutured with cotton produced the least reaction and healed sooner, and therefore cotton was graded first, silk, linen, and catgut were graded in the order mentioned

hospital from the effects of the lesion. One hundred and sixteen left the hospital, and 2 of these later had resections at other hospitals. One died of the operation and the other died in 18 months of recurrence. Six of the 116 have not been followed. Five patients are still living after 6 years, 1 year 4 months 4 months, and 3 months, respectively. Aside from 3 in interesting survivals of 14 years, 13 years, and 6 years with electrocoagulation and radium and 1 survival of 4½ years with radium alone, there are no other survivals over 3 years and the average is 15 months. These unusual cases are discussed under radium treatment.

Effect of radium. Thirty-six patients with inoperable lesions received radium. Three of these were not followed. Twenty-seven of these have died in less than 3 years. Six patients survived 3 years or more and their histories are briefly presented in Table VI.

TABLE VI.—RADIUM TREATMENT

Survival in years	Grade	Dose in rads	Other treatment	Present status
14		3,300	Electrocoagulation	Dead of carcinoma
13½		2,300	Electrocoagulation	Living and well
6		1,450	Electrocoagulation	Living and well
4½	M biopsy	2,300	None	Dead of carcinoma
	M biopsy	2,975	None	Dead of carcinoma
2	(psyl)	975	None	Dead of carcinoma

*This patient was a 41 year old white female who was considered inoperable. She received radium treatment, electrocoagulation, and had colonostomy performed for obstruction. Tumor was grade 3 by biopsy. Thirteen years later patient returned complaining of rectal pain and discharge of pus and blood having been previously well. After another examination was decided that the tumor was operable and it was resected by posterior operation. The tumor was grade 3 and was again biopsy likely that was recurrence of the original growth. The patient has survived 2 years to date following the operation and quite well.

It is interesting that the 3 best survivals with radium are grade 3 tumors. As these patients also received electrocoagulation treatment of the local growth we hesitate to draw any conclusions. The survival of 1 patient with an inoperable growth for 13 years, when the growth was resected, in spite of electrocoagulation and radium, leads to interesting speculation about our criteria for inoperability.

Of the 37 patients who received radium treatment for carcinoma of the rectum there is a record of biopsy confirmation of the diagnosis in only 19. In all but 1 of these unconfirmed cases patients have died with unmistakable carcinoma. In 1 case the lesion later

proved to be an inflammatory one and patient has survived 14 years without evidence of carcinoma being present.

SQUAMOUS CELL CARCINOMA OF THE ANUS

There are 10 cases of squamous cell carcinoma of the anus in the series. Five were in males, 5 in females. Seven were black and 3 white. The average age was 56 years, varying from 32 to 75. The average duration of symptoms was 11 months. The presenting symptoms were local pain in 7 cases, constipation and/or diarrhea in 5 cases, blood in the stool in 3 cases, and an anal mass in 3 cases.

Three were resected by posterior operation. One is living and well 3½ years after operation. This patient also has an associated lymphogranuloma inguinale. One is living and well 1 year after operation. One died of heart failure 4 months after operation. In 5 cases the lesion was electrocoagulation excised. Two of these patients died at operation, one of pulmonary tuberculosis, the other of general debility and infection associated with a neglected extensive growth. The other 3 died of recurrence and metastases in 2 years, 4 months, and 3 months respectively. The latter 2 had inguinal metastases at the time of operation. One patient had an extensive local lesion extending into the buttocks. No operative procedure was carried out but he received a course of radium. He has survived 6 months to date. One patient had metastases to the femur with an extensive local lesion. He received no treatment and died of carcinoma in 3 months.

CONCLUSIONS

Carcinoma of the colon and rectum is a relatively slowly growing and late metastasizing tumor. There is usually present an associated inflammatory reaction which clinically cannot be distinguished from the growth. Fifty per cent of the regional node biopsies at laparotomy are inflammatory.

Operability should be higher. The chances of survival of the untreated cases are poor at best. The chances of survival of the patient who has an adequate excision of the growth and survives the operation are good.

Pathological grading of these tumors is of no significance in this series of cases. A glance

LOCALIO, HINTON CHOICE AND USE OF COTTON FOR SUTURES

Simple wetting of Handcraft cottons caused a decrease of 2 to 6 per cent. Handcraft cottons boiled for 10 minutes and tested while wet increased 2 to 11 per cent, drying caused decreases of 2 to 23 per cent, rewetting or re-boiling for 10 minutes re-established the original increase provided the cottons were tested while wet. Boiling Handcraft for 20 and 30 minutes caused no significant change if tested wet, drying, however, decreased the tensile strength 2 to 23 per cent. This decrease could be abolished by rewetting for 10 minutes in all the sizes except No. 000 and No. 00, which continued to show decreases of 10 per cent and 12 per cent in spite of rewetting, after having been boiled for 30 minutes. Throughout these tests, these cottons varied 7 to 37 per cent. Monarch, Kerr, Clark, and American Thread and LeRoy mercerized cottons showed similar trends of increased tensile strength after boiling, if tested wet, decreased tensile strength below control figures if allowed to dry, and increase above control figures if rewet. The increases were more marked than those observed for Handcraft cottons.

Determination of actual diameters varied considerably for cottons of different manufacture, but of the same stated size.

ANALYSIS OF STUDY

From the data presented, it can be readily seen that cottons of the same number but different brands vary considerably in their actual diameters and tensile strengths. This variation is not always due to greater diameter, for certain brands of cotton of lesser diameter have a greater tensile strength.

The choice of cotton suitable for surgery is dependent on several factors, and the surgeon is cautioned against the use of just any cotton. The cotton chosen should have the greatest tensile strength for its actual diameter, manufacturers' sizes and grading being variable and unreliable.

In order that the surgeon utilize the greatest possible strength of cotton and thereby use the finest possible suture, we suggest that cotton be sterilized by boiling 10 to 20 minutes and used while wet. The method employed at the New York Post-Graduate Hospital, which has been found simple and convenient, con-

sists of winding cotton on machine bobbins which are boiled with the instruments. After sterilization, the bobbins either can be kept wet by immersion in sterile saline or, if allowed to dry, can be wet just prior to use. Individual ties are removed from the bobbin by the operator and individual sutures are removed by the nurse.

For ligation of small blood vessels, Handcraft No. 000 cotton (0.007 inch) with a tensile strength of 2.5 pounds has been used. Larger blood vessels are ligated with Handcraft No. 00 (0.0075 inch) or Handcraft No. 0275 and 3.25 pounds, respectively. Fascia and peritoneum have been sutured with either Handcraft No. A-40 (0.012 inch) with a tensile strength of 3.75 pounds or Kerr No. B-36 (0.0115 inch) of a comparable tensile strength. The same cotton has been employed for intestinal anastomosis. Heavier cottons have not been found necessary, provided interrupted sutures are used. The holding ability of any suture is limited by the tensile strength of the tissue (5, 11) and hence the tensile strength of any suture should not exceed that of the tissue in which it is placed. The tensile strength of a suture line of interrupted sutures, provided a sufficient number of sutures are used, may be made equal to that of the tissue, although the tensile strength of the materials used be less than that of the tissue (6).

All sutures and ligatures were tied with true square knots and cut 1 to 2 millimeters from the knot. No difficulty was encountered in the use of wet sutures and ligatures.

The very low cost of cotton makes it practical to discard all unused material. To avoid confusion and error it is suggested that cottons of different sizes be dyed different colors and iron dyes be used in preference to coal tar dyes.

The variation in tensile strength of cotton may possibly be corrected by the manufacture of better surgical cottons, however, if interrupted sutures are used, the disadvantage of this variation will diminish. Of the cottons tested, those which best meet the criteria enumerated are Gudebrod Brothers Handcraft Nos. 000, 00, 0, and A-40, and Kerr's larger sizes Nos. A-40, B-36, and C-30.

The present study was undertaken to determine the type and brand of cotton best suited to surgery and the most efficacious method of sterilization. Thirty-six grades of cotton of 8 different brands, 24 grades of silk of 3 brands, and 5 grades of linen of 1 brand were tested. Studies were done on a Suter single strand tester. The tensile strength of 10 consecutive single strands was determined. The average and the percentage variations of these 10 readings were calculated. The sutures studied were tested as they came from the manufacturer also after autoclaving after wetting after boiling, and tested wet after boiling and tested dry after boiling drying and rewetting and after boiling drying and reboiling. The average tensile strength of the materials as they came from the manufacturer was accepted as a base line and the percentage change in tensile strength after exposure to the various conditions enumerated was calculated.

SILK

The variation in tensile strength for braided serum proofed silk was below 10 per cent, and for twisted silk below 20 per cent. The tensile strength of Deknatel serum proofed silk increased after autoclaving. After 40 minutes the increase was 3 to 10 per cent, after 80 minutes 6 to 12 per cent, and 5 to 18 per cent after 120 minutes. Paré serum proofed silk showed no change after 40 minutes of autoclaving, an increase of 0 to 13 per cent after 80 minutes, and changes of minus 3 per cent to plus 6 per cent after 120 minutes.

Paré serum proofed silk of the various sizes when boiled for 10 minutes and tested while wet, decreased in tensile strength 0 to 25 per cent. If the same material was allowed to dry it increased in tensile strength 0 to 25 per cent, rewetting decreased the tensile strength 0 to 25 per cent. Champion twisted untreated silk, when boiled for 10 minutes and tested wet, decreased in tensile strength 18 to 39 per cent; this decrease was reduced to 0 to 16 per cent after drying. Autoclaving or boiling did not change the percentage variation of any of the silks tested.

LINEN

Linen autoclaved for 40, 80, and 120 minutes decreased in tensile strength 0 to 18 per

cent. The increase in tensile strength of No. 50 linen is not significant. Linen boiled for 10 minutes and tested wet increased 8 to 34 per cent. This increase was practically abolished by drying and was again apparent after rewetting. The percentage change of dried previously boiled linen was plus 0 to 8 per cent, and for the same material after rewetting plus 16 to 30 per cent. The percentage variation in tensile strength of the linens studied was 10 to 51 per cent.

COTTON

Handcraft cottons decreased 4 to 23 per cent after autoclaving for 40 minutes, 9 to 23 per cent after 80 minutes, and 5 to 23 per cent after 120 minutes. The percentage variation of Handcraft cotton was 6 to 44 per cent. Serum proofed cotton of the same brand was 12 to 35 per cent weaker, but the smaller sizes, No. 000 and No. 00 increased 4 to 15 per cent after autoclaving and the larger sizes decreased 2 to 33 per cent.

Monarch cottons decreased in tensile strength 3 to 10 per cent after 40 minutes of autoclaving, 2 to 9 per cent after 80 minutes, and 0 to 11 per cent after 120 minutes. Monarch No. 0 increased 4 per cent and 7 per cent after 40 and 120 minutes of autoclaving, respectively. These cottons varied in tensile strength 3 to 38 per cent.

Kerr cottons decreased 4 to 10 per cent after 40 minutes of autoclaving and, except for No. 00 to 60 which decreased 7 per cent, showed no significant change after 80 and 120 minutes of autoclaving. These cottons varied 7 to 39 per cent.

Clark cottons showed changes of plus 3 to minus 11 per cent after 40 minutes of autoclaving, plus 3 to minus 20 per cent after 80 minutes and plus 4 to minus 11 per cent after 120 minutes and varied 6 to 40 per cent.

Climax cottons decreased 0 to 11 per cent after autoclaving and varied 11 to 24 per cent. American Thread Company mercerized decreased 0 to 11 per cent and varied 11 to 24 per cent. LeRoy mercerized increased 6 to 9 per cent after autoclaving for 40 minutes and except for a decrease of 9 per cent in the No. 000 size after autoclaving for 80 minutes showed no further significant change. LeRoy cottons varied 6 to 35 per cent.

Simple wetting of Handcraft cottons caused a decrease of 2 to 6 per cent. Handcraft cottons boiled for 10 minutes and tested while wet increased 2 to 11 per cent, drying caused decreases of 2 to 23 per cent, rewetting or re-boiling for 10 minutes re-established the original increase provided the cottons were tested while wet. Boiling Handcraft for 20 and 30 minutes caused no significant change if tested wet, drying, however, decreased the tensile strength 2 to 23 per cent. This decrease could be abolished by rewetting for 10 minutes in all the sizes except No. 000 and No. 00, which continued to show decreases of 10 per cent and 12 per cent in spite of rewetting, after having been boiled for 30 minutes. Throughout these tests, these cottons varied 7 to 37 per cent. Monarch, Kerr, Clark, and American Thread and LeRoy mercerized cottons showed similar trends of increased tensile strength after boiling, if tested wet, decreased tensile strength below control figures if allowed to dry, and increases above control figures if rewet. The increases were more marked than those observed for Handcraft cottons.

Determination of actual diameters varied considerably for cottons of different manufacture, but of the same stated size.

ANALYSIS OF STUDY

From the data presented, it can be readily seen that cottons of the same number but different brands vary considerably in their actual diameters and tensile strengths. This variation is not always due to greater diameter, for certain brands of cotton of lesser diameter have a greater tensile strength.

The choice of cotton suitable for surgery is dependent on several factors, and the surgeon is cautioned against the use of just any cotton. The cotton chosen should have the greatest tensile strength for its actual diameter, manufacturers' sizes and grading being variable and unreliable.

In order that the surgeon utilize the greatest possible strength of cotton and thereby use the finest possible suture, we suggest that cotton be sterilized by boiling 10 to 20 minutes and used while wet. The method employed at the New York Post-Graduate Hospital, which has been found simple and convenient, con-

sists of winding cotton on machine bobbins which are boiled with the instruments. After sterilization, the bobbins either can be kept wet by immersion in sterile saline or, if allowed to dry, can be wet just prior to use. Individual ties are removed from the bobbin by the operator and individual sutures are removed by the nurse.

For ligation of small blood vessels, Handcraft No. 000 cotton (0.007 inch) with a tensile strength of 2.5 pounds has been used. Larger blood vessels are ligated with Handcraft No. 00 (0.0075 inch) or Handcraft No. 0 (0.0085 inch) with tensile strength of 2.75 and 3.25 pounds, respectively. Fascia and peritoneum have been sutured with either Handcraft No. A-40 (0.012 inch) with a tensile strength of 3.75 pounds or Kerr No. B-36 (0.0115 inch) of a comparable tensile strength. The same cotton has been employed for intestinal anastomosis. Heavier cottons have not been found necessary, provided interrupted sutures are used. The holding ability of any suture is limited by the tensile strength of the tissue (5, 11) and hence the tensile strength of any suture should not exceed that of the tissue in which it is placed. The tensile strength of a suture line of interrupted sutures, provided a sufficient number of sutures are used, may be made equal to that of the tissue, although the tensile strength of the materials used be less than that of the tissue (6).

All sutures and ligatures were tied with true square knots and cut 1 to 2 millimeters from the knot. No difficulty was encountered in the use of wet sutures and ligatures.

The very low cost of cotton makes it practical to discard all unused material. To avoid confusion and error it is suggested that cottons of different sizes be dyed different colors and iron dyes be used in preference to coal tar dyes.

The variation in tensile strength of cotton may possibly be corrected by the manufacture of better surgical cottons, however, if interrupted sutures are used, the disadvantage of this variation will diminish. Of the cottons tested, those which best meet the criteria enumerated are Gudebrod Brothers Handcraft Nos. 000, 00, 0, and A-40, and Kerr's larger sizes Nos. A-40, B-36, and C-30.

In a comparison of the tensile strength of suture materials before sterilization, if the actual diameter in inches is used for comparison size for size, silk has the greatest tensile strength. The tensile strength of silk increases slightly after autoclaving but decreases after boiling if tested wet. When one considers the decrease in tensile strength of wet silk and the increase in strength of wet cotton which is what actually occurs, in a wound, size for size, silk and good cotton are comparable.

During the past 5 months more than 50 major surgical procedures have been performed with the use of cotton throughout. These include gastric resections, colon resections, radical mastectomies, cholecystectomies, appendectomies, thyroidectomies, hernioplasties, suture of a perforated duodenal ulcer and pelvic procedures.

In these cases, cotton was used in 8 in the presence of infection. Three developed wound complications, 2 of which were wound infections in cases of acute gangrenous appendicitis which healed without sinus formation and the third a draining sinus of 5 weeks' duration in a case of tuberculous lymphadenitis from which pieces of cotton were extruded. Wound healing in the remaining cases has been excellent.

The cost of cotton makes it possible to perform a major surgical procedure for a few cents as compared with twenty-five cents to a dollar and a half for silk, one to three dollars for catgut. In institutions with active surgical services the use of cotton can effect a saving of several thousands of dollars a year.

CONCLUSIONS

1. Cotton chosen for surgical use should be limited to that showing the greatest tensile strength for the smallest diameter and the least variation.

2. Cotton should be boiled 10 to 20 minutes and used while wet.

3. Cotton has been shown to decrease in tensile strength after autoclaving and to increase after boiling provided it is tested while wet. If allowed to dry after boiling, cotton decreases in tensile strength. This decrease can, however, be abolished by rewetting or reboiling.

4. The principles of silk surgery advocated by Halsted should be adhered to in using cotton.

5. Cotton has been used in more than 50 major surgical procedures and has been found to be a satisfactory and economical suture material.

THE PREVENTION OF HUMAN BITE INFECTIONS

RICHARD E. SPEIRS, M.D., Dodge City, Kansas

THE devastating effects of infection by organisms from the mouth of the human, especially when it involves the hand, is commonly termed "human bite infections" even though the original trauma is not inflicted by the teeth. The gangrenous sloughing infection of the hand so well described in the classic work of Mason and Koch is not so common as one might suspect from the frequent contamination of wounds by mouth organisms. The incidence of contamination of wounds by mouth organisms is undoubtedly great due to the frequency of thumb sucking, hangnail biting, and other habits which bring saliva into contact with wounds. Since the incidence of infection from such contamination is low, it is quite usual that the patient, and sometimes the doctor as well, underestimates the importance of such infections when they occur. Once infection has resulted from such contaminated wounds, the treatment is so difficult and so likely to result in loss of tissue and function that prophylaxis is important. Efforts to prevent infection have generally been quite radical. Bates reported the use of electrocauterization in 100 cases of early human bites with extension in but 1 case. Lowry reported 122 cases treated early by cauterization or by excision. Of these 93 involved the fingers or hand, but 55 of the 122 cases were observed until complete healing resulted, the average time for healing being 14 days. Cauterization by heat or chemicals is advocated by Dimtza, Dunn, Welch, McMasters, and others, as preferred preliminary treatment. In 1930, Mason and Koch suggested that immediately after a human bite injury, the wound be cleansed gently but thoroughly with soap and water and then débrided only of obviously damaged tissue be performed. This simple procedure which does not add material-

ly to the devitalization of tissue appealed to us as of fundamental importance. Accordingly, we have applied this treatment to the patients we have seen at the Detroit Receiving Hospital during the past 2 years. The routine procedure adopted was as follows. The area about the wound was carefully washed with soap and water after which the wound was gently but thoroughly sponged with soap and water for 10 minutes. When the injury was on the hand an effort was made to determine the extent of the injury, but the wound was not probed. Function of the fingers was noted and if injury to a tendon or joint space was evident the tissue was retracted gently and irrigated with physiological salt solution. If injury was evident in the extensor tendon or joint space, the wrist was splinted in hyperextension. Such wounds were dressed in dry sterile gauze and no attempt made to repair the tendon or joint capsule. When there were associated fractures these were splinted, and, in addition, in the case of compound fractures of the phalanges, the wounds were washed and then irrigated with physiological salt solution and saline compresses applied. No effort was made to close the wounds other than to hold the tissues loosely in approximation by means of the dressing. Patients with compound fractures in association with human bites were hospitalized for observation.

Human bites occurring in other parts of the body, especially the nose, ear, and lip were carefully cleansed with soap and water, devitalized tissue carefully débrided and the wound sutured, if this were possible, without too much tension.

While this was the routine followed in the majority of cases, slight variations from this technique were occasionally made, chiefly because early after the routine was instituted it was difficult to change technique and viewpoint immediately. Reliance on antiseptics frequently inaugurates a ritual which is changed slowly and with difficulty.

Treated by phenol or silver acid without washing

Cases refused treatment

a. Returned clean

b. Evidence of inflammation but did not suppurate

c. Became grossly infected

*Did not return for follow-up.

One hundred and fourteen cases of human bites were seen within a few hours after injury. 82 of which were treated strictly by the procedure here outlined, the remaining 32 having some variation of the procedure. Table I gives detailed information concerning these cases.

In none of the 82 patients treated by the method outlined were there any whose wounds became infected, except 2 over the knuckle which were sutured. Seven of the 14 patients who were treated with phenol and alcohol developed more evidence of inflammation than usual wounds became red, swollen and indurated but did not suppurate. Two patients with knuckle injuries, which were cleansed and sutured, required hospitalization. One returned 8 hours after the preliminary treatment. The

sutures were removed and wet dressings applied. Twelve hours later drainage was advised but the patient left the hospital against advice. The second patient came back 4 days after preliminary treatment and required drainage of a seropurulent exudate from the dorsal subaponeurotic space and excision of a portion of the extensor tendon. The hand was splinted in hyperextension and saline soaks were applied. The wound healed well and resulted in a normally functioning hand. One other hand was sutured but the patient did not return therefore the results are unknown. Nine other patients were admitted to the hospital for observation immediately after preliminary treatment.

The results in this group of cases have been gratifying especially in comparison to former experiences with cauterization, excision, or extensive cleansing with strong chemical agents. The comparison of these results with those in the literature in which radical prophylactic measures have been taken, have confirmed our belief that observation following cleansing of the wound with soap and water within the first few hours after the injury is the method of choice for prophylaxis of human bite infections. We are impressed also that by this means the healing time of the wound is shortened and tissue destruction minimized. In 35 patients the average time for complete healing was 7.8 days. In 60 other patients it was felt that healing had progressed sufficiently far to discharge them in an average time of 4.9 days.

The recognition of human bites on the body is generally easy for there are usually abrasions, contusions, petechiae, and tooth marks present. Those on the nose, finger or knuckle may be more difficult to recognize. Over the knuckle there is usually a clean penetrating wound $\frac{1}{2}$ to 1 centimeter long, which may appear to be superficial but if the patient will make a fist it frequently will bring a partially severed tendon into view or reveal an opening into the joint space. It is important to know the extent of the injury but not to the point where probing is indicated. This may not only fail to disclose small openings in the underlying tissue but it may result in the accidental spread of infection to a deeper layer

or open the joint space. It seems better to wash the wound and treat it kindly and gently. Daily observation of the injury to note inception of infection is indicated. In this group of cases there was one patient with an extensor tendon completely divided, as ascertained by the function of the fingers. No attempt was made to suture the tendon or close the wound, as we believe that this is contra-indicated in such potentially infected wounds. It is a good rule to consider any small penetrating wound on the hand as a human bite until proved otherwise, especially if this seems likely from the appearance of the wound, for it is a mistake to close such wounds primarily.

Bites on the fingers are generally on the distal phalanx. They vary from simple abrasions to compound fractures. In our series there were 3 of the latter. It is of interest that in each case the teeth penetrated the nail and did not leave any mark on the palmar surface. Bites on the distal phalanx are potentially dangerous and should be watched for the development of a felon or tendon sheath invasion. One case was seen in which the flexor tendon sheath had been opened and the tendon partially severed, but infection did not occur.

Injuries to the lip ranged from penetrating wounds to almost complete avulsion, the latter being more common. Many of these wounds result from the patient's own teeth during fighting, others, which were usually more extensive, resulted from bites by others. The amount of tissue removed varied considerably but in most instances removal extended into 1 or 2 by 3 centimeters. In 1 case an immediate pedicle graft was done and a good result obtained. In the other patients, in whose cases smaller amounts of tissue were missing, the wounds healed nicely by granulation without notable deformity.

For the most part, bites of the nose were extensive, going through the ala, severing the cartilage, the severed portion being attached only loosely over the bridge of the nose. Before a more careful study was instigated, no effort was made to get a cosmetic result

because the danger of infection with extension via the infra-orbital vessels was feared. Since we have utilized careful cleansing, we have felt that loose approximation is permissible and have seen no ill results to date. Bacteriological studies and smears were not made in this group of early cases, and we have no data regarding the degree or type of contamination present.

SUMMARY

One hundred and fourteen cases of human bite given prophylactic treatment within the first few hours of the injury are presented.

Careful cleansing with soap and water in 82 of the cases was sufficient to prevent infection. In 35 cases followed to complete healing the average time required was 7.8 days.

Three of 14 patients treated by cauterization with phenol and alcohol gave evidence of inflammation but the wounds did not suppurate.

In 2 cases of human bite of the hand in which primary closure of the wound was carried out in addition to cleansing with soap and water the wounds became infected and required hospitalization.

These data when compared with previous reports would suggest that careful washing of early human bites with soap and water is preferable to other forms of immediate treatment whether it be chemical or electrocautery or surgical excision.

I wish to thank Dr. Don M. Morrill, superintendent of the Detroit Receiving Hospital, and my colleagues in charge of the emergency room, Drs. A. Z. Howard, B. R. Richey, J. R. Brown, and A. Finch, for their co-operation in allowing me to see and treat the majority of these patients.

THE TREATMENT OF RUPTURE OF THE URETHRA ESPECIALLY WHEN ACCOMPANYING FRACTURES OF THE PELVIC BONES

J HARTWELL HARRISON M.D Boston, Massachusetts

THE increasing hazards of civil life lead each year to an increasing number of severe accidents. Injuries to the urethra are no exception to this statement once relatively rare traumatic lesions, they are now seen with sufficient frequency to necessitate detailed consideration. This is particularly important inasmuch as urethral injuries are usually caused by fractures of the pelvic bones and by "straddle injuries" to the perineum, lesions which often bring patients to surgeons not especially concerned with conditions of the genito-urinary system. It seems appropriate, therefore to consider in a journal of general circulation a group of patients with rupture of the urethra at various levels and to discuss the treatment with particular reference to those lesions accompanying fractures of the pelvis.

This paper is based on a series of 21 instances of rupture of the urethra treated in the Peter Bent Brigham Hospital. Of these 21 cases 12 involved the bulbous urethra and 9 the membranous urethra. All 9 patients who sustained rupture of the membranous urethra suffered this injury as a result of fracture of the pelvis. They presented far more complicated problems in diagnosis and treatment than the other group. It is natural that in the literature on this subject there has been particular emphasis on the management of visceral injuries, which are more obvious but not always more significant than the injury to the urethra and to the pelvic bones. Attention has been directed primarily to immediate life-saving measures, and little has been said regarding the prolonged postoperative and convalescent care of these patients. There is especially lacking a consideration of the simultaneous treatment of injury of the urinary tract and fractures of the pelvic bones. In a group of 160 patients with fracture of the pelvis, there were 9 patients whose fractures were complicated by rupture of the membranous urethra, only 4 who had rupture of the bladder. In our experience patients with rupture of the

membranous urethra are extremely difficult to manage, both from the standpoint of control of infection and of maintenance of a satisfactory position of the pelvic girdle. Although we have made free use of the available literature on various phases of rupture of the urethra, our methods have been worked out largely independently according to the requirements of the individual case. The literature on the subject is cited in the references at the end of this paper. A detailed review seems out of place in the present communication.

Fractures of the pelvic bones which are likely to be accompanied by urethral injury are produced by various crushing forces. The mechanism of injury is the lateral compression of the pelvic girdle, which causes collapse of the pubic and ischial arches and often fracture of the sacrum as well. The fragments (Fig. 1) of pubic and ischial rami are displaced medially posteriorly and downward, tearing the triangular ligament and its enclosed structures, notably the membranous urethra, pudendal vessels, and the voluntary sphincteric muscle. Fragments of pelvis or hemipelvis may be driven into the bladder tearing its wall either anteriorly or inferiorly lateral to the trigone and usually outside the peritoneal sac. However intraperitoneal rupture of the full bladder may occur as a result of the same forces that cause the fracture of the pelvis.

When a patient has sustained a crushing injury to the bony pelvis, the immediate problem is to determine the extent of internal injuries at the same time that energetic measures are being instituted to combat shock. The intense pain requires repeated administration of morphine provided there is no cranial injury. Temporary immobilization of the pelvis and extremities on a Bradford frame with the aid of sandbags is imperative. Failure to do this increases shock. A support under the knees for slight flexion of the thighs lessens pain by relieving muscle spasm. Besides the usual chart of blood pressure pulse and respiratory rates, repeated hematocrit and specific gravity studies of the blood are helpful in guiding the administration of parenteral fluids. Investigation of the urinary tract should be de-

From the Department of Surgery of the Harvard Medical School and the Urological Service of the Peter Bent Brigham Hospital, Boston. Read before the New England Regional Fracture Committee of the American College of Surgeons, May 25, 1940.

Fig 1 Roentgenogram of pelvis and diagram to show fractures of pubis, ischium, and sacrum caused by cave in of a gravel bank upon a man aged 23 years, which resulted in complete rupture of the membranous urethra and laceration of pudendal vessels. There was extensive retrovesical and retroperitoneal hemorrhage which extended up between the leaves of the mesentery and interfered with the circulation to the bowel. Abdominal exploration and suprapubic cystotomy were performed, and 11 months later plastic repair of the urethra was successful.

layed until the patient is seen by the surgeon who will have charge of his case. Enthusiastic instrumentation in the emergency room has often been misguided, and better evaluation is obtained after prompt transfer to the surgical ward.

Even in patients with fractures of the pelvis without injury to the urinary tract, inability to void at the time of admission is common since both shock and pain inhibit micturition. It may be difficult to elicit evidence of an injury to the urethra until some time has elapsed. The patient may have emptied the bladder a short time prior to the accident. It is also true that the hemoconcentration resulting from shock diminishes renal excretion. The presence of blood at the external urethral meatus contributes evidence of ruptured urethra.

After these preliminary considerations one may proceed with further details of examination. Intraperitoneal hemorrhage or urinary extravasation from rupture of the bladder causes diffuse abdominal tenderness and rigidity. The former is attended by signs of profound shock, which usually progresses rapidly and responds poorly to supportive measures. Extraperitoneal extravasation of blood and urine produces lower abdominal pain, tenderness, and muscle spasm. If the bladder is intact and the membranous urethra ruptured, the former may be palpated as a symmetrical rounded mass rising up out of the pelvis in the midline. When the bladder is ruptured, that organ will not be palpable. There may be, however, a mass in the suprapubic region or in an inguinal region as a result of extravascular urinary extravasation. A deformity of the pubic bone may be palpated, and gentle examination may elicit

crepitus. Tenderness over the sacro-iliac joints is due to the fracture itself, not to its complications. Paralyzes, anesthetics, paresthesias, and severe radiating pains in the extremities may result from injury of sacral nerve trunks. Careful rectal examination is of utmost importance in diagnosis. If the prostate gland is not palpable and the rectum is felt slightly com-

Fig 2 Diagrammatic sagittal section showing bladder and prostate separated as a unit from the urethra by laceration of its membranous portion and the urogenital diaphragm. Note the retrovesical hematoma and extravasation of blood and urine up into the prevesical space. The intrinsic vesical sphincter closes after such an injury and clear urine is usually found in the bladder at operation if that organ itself has not been injured. This diagram represents the findings at operation in 3 of our cases and is very similar to the condition described originally by Young.

Fig. 3. Roentgenogram of the pelvis of a man aged 45 years made with the portable unit while shock was being combatted. The indwelling urethral catheter does not reach the bladder but goes off to one side in the ischio-rectal fossa from which it drained 500 cubic centimeters of bloody fluid during the course of 4 hours. At operation the membranous urethra, as found to have been completely severed, the bladder as intact and contained 500 cubic centimeters of clear urine. Immediate restoration of the continuity of the urethra as accomplished (see Fig. 5).

Fig. 4. Roentgenogram of pelvis and hips of man aged 45 years, he fell a distance of 40 feet landing on his left side. There are fractures of left pubis, ilium, ischium, and neck of the femur. There is no visible displacement that could injure urethra or bladder. One can discern a symmetrical rounded shadow in the pelvis which is probably a full bladder. The patient, as not catheterized, and 4 hours after injury of or relief of pain and shock, he voided 500 cubic centimeters of normal urine.

pressed by a soft mass in the pelvis, a complete rupture of the membranous urethra is certain. It indicates that the prostate and bladder have been torn from their attachments and displaced upward as a unit by the retrovesical hematoma (Fig. 3).

Hemorrhage and urinary extravasation may cause both swelling and discoloration of the perineum. The location and nature of such extravasations is of considerable diagnostic importance. At times these signs do not appear for several hours, and repeated examination must be made for them. Following rupture of the membranous urethra the perineal mass appears later and is likely to become diffuse. If the swelling and discoloration appear immediately and are confined wholly or in large part to one side of the perineum the rupture has probably occurred in the bulbous rather than the membranous urethra. The presence of a mass in the suprapubic region or inguinal region indicates either a rupture of the membranous urethra and urogenital diaphragm or of the anterior wall of the bladder. When the two layers of the urogenital diaphragm are torn, hemorrhage from the pudendal vessels and urine from the urethra is permitted to escape freely into the perineal tissues, periprostatic spaces, and directly up into the prevesical space.

A catheter may be passed, but complete urological investigation is not necessary in every patient who cannot void after an accident, especially in the presence of a negative roentgenogram as

will be discussed. If the catheter seems to be in the bladder it should be left in place for the present. In general irrigation should be unobtrusively avoided. Keyes mentions it only in condemnation, and our experience confirms this teaching. At times it may be justifiable gently to irrigate the catheter with about an ounce of saline or boric acid solution in order to insure its patency and freedom from obstruction by clotted blood. There may be difficulty interpreting observations made during the passage of the catheter since it is sometimes uncertain whether the catheter is actually in the bladder and also whether the primary injury is to the bladder or urethra. It is usually impossible to pass a catheter into the bladder when the membranous urethra is ruptured. In this case the catheter may pass into the prevesical space or ischio-rectal fossa. Withdrawal of bloody fluid may lead the surgeon to believe that not only is the catheter in the bladder but that the bladder itself is ruptured. In the passage of the catheter it must always be remembered that a partial rupture of either the bladder or the urethra may be converted into a complete rupture by careless or unduly forceful instrumentation.

Powers and Smith have emphasized the value of suprapubic cystostomy and retrograde instrumentation of the urethra. They used the latter maneuver to discover whether the instruments passed through the urethra emerged through the external orifice or whether they passed off into a false passage before reaching the bladder. They

HARRISON THE TREATMENT OF RUPTURE OF THE URETHRA

suggest removing the urethral tube in 12 to 14 days and leaving a filiform in place to act as a splint. The length of time suitable to have the urethral catheter in place is arbitrary and varies in different cases. We have left such a tube in place as long as 6 weeks. Also, we use the urethral catheter as a source of drainage of the bladder and believe that this protects the site of rupture from urinary leakage. If the catheter causes a purulent urethritis and systemic reaction, it should be immediately removed, and a silk thread attached to the abdominal wall, left in the urethra, to act as a splint.

A portable roentgenogram of the pelvis is of great importance in determining the extent and character of the injury. It serves to indicate not only the type of fracture present, but also whether the catheter, previously inserted, follows the course of the urethra into the bladder or whether it veers into the perineum as happened in one of our cases (Fig 3). In determining the position of the catheter, the surgeon may correlate these findings with rectal palpation. The roentgenogram may give valuable aid in ruling out rupture of the urethra, for it may show multiple fractures of the pelvis without such displacement of any fragment as to cause injury of either urethra or bladder. Also, such a film may show the rounded symmetrical shadow of an intact full bladder (Fig 4). Expectant treatment in such cases is desirable and voiding will often take place normally once immobilization of the pelvis and extremities. The pain has been relieved by sedation and proper once prevalent teaching, that every such patient should be immediately catheterized, is not now tenable.

Cystoscopic examination of patients who have sustained violent trauma is obviously contraindicated. Immediate excretory urography is not an appropriate procedure for the patient in shock but may be helpful later, particularly when renal injury is suspected in addition to the trauma to the urinary passages. The use of the urethrogram should be delayed usually for 3 to 6 weeks after trauma. At the end of that interval it is advisable to use this method to determine the state of the urethra after regeneration has taken place. It is conceivable that rupture of the urethra may be ruled out early in mild doubtful cases by means of this procedure.

For rupture of the urethra at or above the triangular ligament, suprapubic cystotomy should invariably be performed. At operation all blood and urine are aspirated from the prevesical space. The bony fragments are elevated from the lacerated urethra. Simultaneous manipulation of the

Fig 5 Diagrammatic representation of operative manipulation in which the right index finger is passing into the bladder outlet in order to thread it over the end of sound in the distal end of ruptured portion of urethra

lower extremities by an assistant may facilitate this maneuver. The bladder is opened and examined for evidence of injury. A sound is passed through the penile urethra and guided in its passage to the displaced prostatic urethra by the index finger of the right hand placed in the orifice of the vesical outlet (Fig 5). The end of a catheter is inserted over the end of the sound in the bladder and drawn in a retrograde manner through the urethra, thus re-establishing its continuity. A silk suture is passed through the proximal end of the catheter in the bladder and its end attached to the abdominal wall. A drain is left in the prevesical space and the bladder closed with a de Pezzer catheter in place. The patient's legs are then flexed in slight abduction and perineal section performed quickly to establish drainage of blood and urine accumulated in the perineum. Immediately after operation the patient should be immobilized on a Bradford frame and the region of the sacrum and buttocks protected by a sponge rubber pad. Further immobilization of the pelvis and more satisfactory alignment of the fragments of the bones may be obtained by a Russell type of traction applied to both legs. By regulating the weights for traction on each extremity according to the deformity present, structural defects can be corrected and further distortion prevented. This method permits support of the thighs and longitudinal traction simultaneously, thus allowing the extremities to swing free without exerting an undesirable drag on the pelvis. The excellent results obtained by this method of treatment are well shown in Figure 6. In several days, as soon as the patient's general condition permits, anterior and posterior body shells of plaster should be made to allow turning to avoid decubitus ulcer. Prevesical drainage is facilitated when the patient is placed so that he is lying on

Fig. 6 (left). Roentgenogram of pelvis 3 months after fractures of pelvis, ischia, and sacrum accompanied by rupture of urethra. Note only slight narrowing of pelvis and good horizontal alignment of acetabulum and iliac crests. The patient obtained also an excellent functional result and—as sliding—fib support of crutches 1 this time. Contrast with Figure 7.

Fig. 7. Roentgenogram of the pelvis 3 months after fractures of the pelvis, which originally appeared as in Figure 1. Note the undesirable results, namely: narrow, heart-shaped pelvis, poor alignment of level of acetabula and ilia, medial collapse of pubic arch, and rotation of entire right side of pelvis. The functional result is not good, the patient walks with difficulty; there is marked gait—algia, and he suffers constantly with low back pain. This is common result from use of the pelvic sling. Contrast with Figure 6.

his abdomen. However extreme edema of the penis and scrotum may be anticipated if the patient is left in this position more than a few hours. Frequent change of position is required if the edema becomes severe. Physiotherapy is imperative early in the course of treatment to lessen muscle atrophy. The prevention of permanent abnormality of gait and posture is a major consideration sometimes overlooked in the early care of these patients. We have not obtained good results with the pelvic sling. Patients treated in this way are often left with a narrow "heart shaped" pelvis which causes more disability than is the case when the pelvis is too wide (Fig. 7). Fragments of pubic bones may become infected and are sometimes extruded spontaneously.

Decubitus ulcer is a common complication that assumes grave importance if not anticipated and treated promptly. For a completely successful result these complications must be prevented by early recognition and treatment at the same time that restoration of the urinary tract is under taken.

At an appropriate time several weeks after operation the urethral catheter is removed. The suture attached to its vesical end is drawn down through the urethra, and its other end is left attached to the abdominal wall by way of the bladder and suprapubic sinus. The urethra is

then filled with radio-opaque material and an exposure is made with the portable roentgenographic unit (Fig. 8). If there is no extravasation of the opaque fluid the catheter is not replaced, but the silk thread is retained as a guide for the passage of instruments. When the surgeon is certain that the urethra is healed and has an adequate lumen, the suprapubic catheter may be removed, the fistula is allowed to close, and neostomization then takes place through the urethra. At this time there is the greatest danger of the appearance of acute pyelonephritis as a complication. Frequent cultures of the urine are made and appropriate chemotherapy instituted if infection is detected. Calibration of the urethra is carried out twice a week, dilatation is made slowly in order to minimize the extent of periurethral fibrosis. The development of some degree of urethral stricture is inevitable in all of these patients. Post-traumatic strictures are more difficult to manage than those of infectious or congenital origin. The degree of constriction may vary but in any event must be checked at intervals throughout the rest of the patient's lives. A serious predicament results when they are neglected and allowed to contract. This is well illustrated in Figure 9, a roentgenogram of a patient who, after 1 year of successful treatment, allowed his condition to be neglected for 3 years. It is now impossible to ob-

Fig 8, left Roentgenogram of pelvis, urethra being filled with skiodan 6 weeks after complete rupture as shown in Figure 2. Complete regeneration has occurred, and there is no evidence of extravasation. The opaque fluid has passed into the bladder.

Fig 9 Roentgenogram of pelvis and urethrogram on patient 20 years after fractures of pelvis and rupture of urethra. Neglect of dilatation of urethra for 3 years has resulted in dense stricture that markedly narrows lumen of posterior urethra. Note fragments of bone displaced down into thigh. The small, round, opaque shadows in the pelvis lie outside of the urinary tract and are probably phleboliths.

tain a urethral lumen larger than No. 18 French in this patient, and even this can be maintained only by frequent dilatation. He has a considerable degree of hydronephrosis and hydro-ureter as a result of the long neglect. Technically, a surgeon undertaking the dilatation of a stricture resulting from trauma must use extreme caution and delicacy in his manipulation. The patient's reaction is an excellent index of the efficiency of instrumentation. If instrumentation is painful, he will not return, and, if he is wise, will go elsewhere for treatment. The slightest sign of blood also is a danger signal, compelling cessation of treatment for that day. Distention of the urethra with a lubricant such as mineral oil, or a mixture of nupercaine and lubricating jelly prior to instrumentation greatly facilitates the passage of instruments.

The seriousness of rupture of the membranous urethra is emphasized by the end-results in a series like the present. In this series, patients have been under the care of the genito-urinary surgeon from the time of admission to the hospital, yet the results, especially when entrance to the hospital has been delayed, have not been brilliant. Two of the patients who sustained rupture of the membranous urethra died on the day of injury as a result of shock from extensive internal injuries. It is apparent in retrospect that in

neither instance was shock combatted adequately according to the modern concept of treatment. Three of the patients having rupture of the bladder died within 1 week as a result of extensive injuries and infection. The other patient, a woman aged 69 years, died 2 months later of bronchopneumonia and renal sepsis. Suprapubic cystotomy and suture of the vesical rupture were carried out in each of these cases, but only one was brought to the hospital on the day of injury. A mortality rate as low as 20 per cent has been reported for those cases in which treatment began within 12 hours after injury. After that period of delay, however, the mortality leaps to 85 to 90 per cent.

Four of the patients having rupture of the membranous urethra were treated by combined suprapubic cystotomy and perineal drainage. In one instance the continuity of the urethra was immediately restored. In another, suprapubic cystotomy was performed initially and 1 month later successful anastomosis of the urethra was made. Suprapubic cystotomy and perineal drainage were established in 2 patients, plastic repair of the urethra was performed 8 and 11 months later, respectively. In another case, a boy aged 7, cystotomy was performed in another hospital and urethroplasty attempted here 9 months later without success (Fig 10). There was a mass of

Fig. 1, left. Oblique urethrogram of boy aged 6 who had sustained complete rupture of the membranous urethra and fracture of the pelvis 9 months previously. Note the extreme irregularity of the canal and particularly the obliteration of the channel at the anal junction. The false passages are apparent, probably occurring from instrumentation. Attempts at plastic repair were unsuccessful owing to dense cicatricial tissue.

Fig. 2. Intravenous urogram 7 years after urethral transplantation into the bowel and total cystectomy. The patient is quite well 6 years later.

cicatricial tissue 5 centimeters in thickness between the urethra and bladder. Two operative attempts to establish a patent canal through to the bladder were unsuccessful. This patient illustrates the error of suprapubic drainage without immediate regard for restoring the continuity of the urethra, or perineal drainage if this is impossible. Finally urethral transplantation into the bowel and total cystectomy were performed. The patient is entirely well today, 6 years later (Fig. 2). The results (Fig. 2) in these cases show that original perineal drainage diminishes the hazard of infection and proliferation of fibrous tissue which so often makes subsequent attempts at plastic repair of the urethra almost impossible. If initial restoration of the continuity of the urethra by catheter or suture is possible, secondary operation is avoided altogether.

The results at other clinics emphasize, as do our own, the seriousness of these injuries. A series of 30 instances of rupture of the urethra were reported from the Massachusetts General Hospital by Smith and Mintz. Thirteen of these were sustained in conjunction with fractures of the pelvis; 9 of these patients died. In 3 cases, death occurred within 24 hours as a result of shock and other injuries. Three patients died much later as a result of sepsis in and about the urinary tract. The 3 others died later of complications not directly related to the urinary tract. Of the 4 patients who lived, 1 had no operation but was drained by urethral catheter for 16 days; recovery

ensued in another 31 days after suprapubic cystotomy and retrograde catheterization; 1 patient was successfully treated by combined cystotomy and perineal section; only cystotomy was performed for 1 patient who was discharged from the hospital bearing a suprapubic tube 7 weeks later. There were 7 patients having rupture of the bulbous urethra without fracture of the pelvis, only 1 of whom died.

Culver reported a mortality of 2 per cent in a series of 18 patients having fractured pelvis and ruptured urethra. Fourteen patients with straddle injuries as the cause of rupture of the urethra all recovered. External urethrotomy was performed in 10 cases, combined in 7 with suprapubic cystotomy and retrograde catheterization of the bladder. Four patients were treated conservatively with good results. His experience showed that, after hemorrhage and urinary retention have been cared for, local sepsis in the perineum causes longstanding urinary fistula and subsequent stricture formation. Proper early surgical management minimizes local infection. Three patients had long periods of hospitalization and some permanent impairment of function because of failure to restore the continuity of the urethra at the same time that suprapubic cystotomy was performed. Later management of these patients consisted of measures to combat urinary infection and to dilate the urethra. It was pointed out that straddle injuries usually occur below the urogenital diaphragm and require

Fig 12 Anteroposterior and lateral views Combined urethrogram and cystogram made 3 months after fracture of pelvis and rupture of urethra showing wide separation of proximal end of urethra and bladder outlet Dense cicatricial tissue has obliterated the posterior urethra as result of failure to restore its continuity at the time of cystotomy The impingement of the displaced fragments of the pubis and ischium on the position of the posterior urethra is graphically shown Successful anastomosis of urethra to bladder was made 11 months after injury

only perineal operation Urethral injuries by pelvic fracture occur in and above the diaphragm and require suprapubic operation We agree with this opinion but feel that, in addition, perineal drainage in these cases lessens local sepsis A satisfactory lithotomy position is difficult to obtain and unwise for a patient who has recently sustained fracture of the pelvis This we believe to be a contra-indication to primary suture of the urethra by way of the perineum in most cases of fracture of the pelvis Young has accomplished the brilliant feat of successfully performing this operation on one patient in the home

This paper has thus far discussed the symptoms and treatment of ruptures of the membranous urethra, especially those accompanying fractures of the pelvic bones Many of the considerations in regard to treatment, however, such as those concerning stricture as a result of the rupture of the urethra, are applicable to injuries at any level of this passage

In the present series of 21 instances of rupture of the urethra, there were 12 cases in which the lesion was in the bulbous urethra as against 9 in the membranous portion Rupture of the bulbous urethra is usually a less serious condition than a corresponding injury to the membranous urethra This is shown not only in the present series but also by other series in the literature, such as that of Smith and Mintz As suggested by the ana-

tomical location, the bulbous urethra is usually ruptured, not as the result of fracture of the pelvic bones, but from a variety of sources of trauma Such injuries may be the result of falls astride sharp objects (4 patients in our series), faulty instrumentation of the urethra by the surgeon (3 instances), and also self-inflicted injury as the result of insertion of foreign bodies in the urethra (5 patients)

Three of the patients having rupture of the bulbous urethra received drainage of the bladder by means of a urethral catheter Later, incision and drainage of peri-urethral abscess was necessary in 2 of these cases Each of the 3 patients was in the hospital for 14 days, and since then regular treatment for urethral stricture has been necessary External urethrotomy was performed upon 3 patients in this group Two were well 2 weeks after injury, and 1 died the day after operation The latter patient, a man aged 52 years, suffered an instrumental perforation of the urethra 1 week before admission to the hospital In 6 days urinary extravasation and infection had caused gangrene of the perineum Also there was noted total retention of urine when he was first seen Immediate perineal drainage was established, and death took place within 36 hours This case is a good illustration of the grave consequences which follow neglect of the presence of extravasated urine

Fig. 3, left. Roentgenogram of the pelvis showing the shadow of glass stirring rod which was introduced into the urethra and spontaneously passed into the bladder. Its distal end was buried in the urethral bulb and was palpable in the perineum.

Fig. 4. Urethrogram 3 weeks after urethrotomy to remove stirring rod from urethra and bladder. This shows the promptness of healing without stricture when the urethra is opened and closed surgically in the absence of urinary extravasation.

Five injuries of the bulbous and penile urethra by foreign bodies have been treated. There was perforation of the urethra by sharp hair pins in 3 cases. Two sharp pointed pencils and glass stirring rod, found in the 3 other patients, were so imbedded in the mucous membrane of the bulbous urethra that removal without operation was impossible. External urethrotomy was performed in each instance, and the successful removal of the intact foreign body accomplished. The pencils and the stirring rod (Fig. 3) had each passed into the bladder and the distal end of each could be palpated at the point of protrusion into the urethral bulb. One patient whose urethra was perforated by a hair pin developed a peri-urethral abscess. A primary closure of the urethra was made in the 4 other cases, and urination was normal at the end of 1 week. An indwelling urethral catheter was required after operation in only 1 of these patients. His temperature rose to 104 degrees the day after operation but returned to normal in 3 days; the catheter was removed after 6 days. The perineal wound healed by primary intention, and a urethrogram 3 weeks later showed no evidence of stricture (Fig. 14). At the end of 3 months no stricture was found when the urethra was calibrated.

If it is determined that a patient has a rupture of the bulbous urethra, immediate perineal section is indicated for control of hemorrhage and urinary extravasation. The use of an indwelling urethral catheter alone will not usually suffice as peri-urethral abscess will always develop in the

presence of urine in the tissues outside the urethra, because extra-urination interferes with local circulation and causes necrosis and infection. Primary closure of the urethra over an indwelling catheter may be carried out but not without increasing the hazard of infection. It is our experience that an external urethrotomy wound that is left open to drain freely will heal quickly once infection in the perirethral tissues is controlled. This method has the merit of safety without unduly prolonged hospitalization.

SUMMARY

The methods used in the treatment of patients having injury of the urethra have been presented. Twelve of these had injury of the bulbous urethra. Nine patients had rupture of the membranous urethra as a result of fractures of the pelvic bones.

Certain points in physical examination and roentgenographic findings that are diagnostic aids have been described. The best results for rupture of the bulbous urethra have been obtained by immediate external urethrotomy whereas the operative management of rupture of the membranous urethra consists of a combined suprapubic and perineal approach, particularly when accompanied by fracture of the pubis and ischium. The important details of simultaneous treatment of the fractures of the pelvic bones have been emphasized. The methods that we have found to give the best results in each type of injury have been outlined.

TRANSUMBILICAL REPAIR OF CONGENITAL UMBILICAL HERNIA

JAMES B. BLODGETT M.D. Boston, Massachusetts

An operative technique is described for the repair of umbilical hernia in children without the production of a noticeable defect.

Small congenital umbilical hernias usually disappear before the age of 3 years. This may occur spontaneously or with the assistance of abdominal strapping. The condition is usually asymptomatic although the child may complain of fleeting periumbilical pains. The complaint of the parent is that the unsightly bulge involving the umbilicus has not diminished or may be increasing in size. The operation for which this technique is applicable is done only when the hernia is increasing in size or is giving symptoms.

REQUIREMENTS OF OPERATION

The surgical repair of congenital umbilical hernia requires the excision of the hernial sac and closure of the fascial ring. It seemed desirable to do this with an inconspicuous scar. An attempt was made, therefore, to carry out the repair by means of a *transumbilical* approach so planned that at the end of the procedure the scar would fall within the cutaneous ring of the umbilicus itself and therefore would be essentially invisible. Fourteen patients have been operated upon with this technique at the Children's Hospital. We have found that the fascial ring can be well closed and that the recti may be united for several centimeters above and below the umbilicus and that the postoperative result is satisfactory.

OPERATIVE PROCEDURE

The umbilicus is cleaned with soap and water prior to the application of the usual skin antiseptic. A "weak" Allis clamp or small double hook is placed on the central portion of the umbilical skin for traction. The umbilicus is everted, and the line of incision is scratched or marked with dye on the skin of the upper portion of the hernia. The scratch is made as a convex upward semicircle so arranged that as the umbilicus is inverted, the mark lies just within the umbilical cutaneous ring (Fig. 1). The upper portion of the umbilical skin is chosen for incision to allow

easier access for closure of the diastasis recti which is more commonly found above than below the hernial ring. The umbilicus is everted and the skin incised with a small blade down the cleavage plane between the skin and the fascial covering of the hernial sac. Over the sac and in the region of the diastasis there is very little fat in the areolar tissue of this plane. The plane is developed by scissors dissection upward along the surface of the inter-rectus fascia and laterally as far as the medial edges of the rectus muscles. In this manner the hernial sac becomes apparent. The dissection should be kept close to the inter-rectus fascia to prevent cutting into the vascular fatty panniculus overlying the anterior rectus fascia. Development of the rectus fascia below the hernia is permitted by cutting off the top of the sac, which is attached to the central portion of the umbilical skin. The plane between the skin and superficial fascia investing the inferior surface of the sac is thus opened for dissection (Fig. 2, a to e). The Allis clamp may now be removed and the skin flap of the umbilicus folded back out of the field.

Hemostats are applied to the margins of the open sac for traction. The anterior rectus fascia should be cleared for 3 or 4 millimeters lateral to the medial edges of the rectus muscles upward and downward to the point where the rectus muscles meet in the midline. The skin incision may be displaced by proper retraction to facilitate the dissection. It is important to locate the position of the medial edges of the rectus muscles beneath the fascia so that they may be properly brought together in the midline. The medial edges of the muscles beneath the anterior rectus fascia are identified (1) by the somewhat gray color imparted to the anterior fascia by the muscle tissue beneath (2) by the perforating vessels which appear through the anterior fascia approximately to the medial edges of the muscles just above and below the umbilicus (3) by the appearance of the edges of the recti, which on elevation and depression of the inter-rectus fascia seem to be relatively tense lateral bands in the loose inter-rectus fascia. After the fascia has been thoroughly exposed, the hernial sac is trimmed off to leave a collar of about 3 to 4 millimeters in width. The neck of the

Fig. 3. Pre-operative and postoperative photographs of relatively large umbilical hernia in two year old child.

fragment of peritoneum is removed to preclude the possibility of fluid being secreted by peritoneal tissue buried beneath the umbilicus (Fig. 3m). The umbilical skin is anchored to either side of the midline fascial approximation by two to four silk sutures so placed as to insure proper reposition of the umbilicus. Fine interrupted silk sutures are used to unite the skin edges. It is found that when the umbilicus has been attached to the fascia, the skin incision is inverted within the umbilical cutaneous ring.

A small roll of gauze is placed in the depression of the umbilicus to maintain the shape of the umbilicus and to promote adhesion of the umbilical skin to the fascia. A dry sterile dressing with wide adhesive tapes is applied. The sutures may be removed at the usual time without difficulty.

Among 14 patients who have been operated upon with this technique there have been no wound infections or postoperative complications. Postoperative examinations have been made on the first 8 cases, 3 to 6 months following this procedure. The results have been entirely satisfactory. Figures 2 and 3 show the preoperative and postoperative appearance of representative cases of umbilical hernias treated with this procedure.

SUMMARY

A technique has been presented for the repair of umbilical hernia in childhood. This procedure has been employed on 14 patients at the Children's Hospital. In each instance it has resulted in a satisfactory cure with a normal appearing umbilicus and an inconspicuous scar.

CARCINOMA ERYSIPELATODES

Subepidermal Lymphatic Metastases Confused with Operative Sequelae

MORTIMER R. CAMIEL, M D, and HERMAN BOLKER, M D,
Brooklyn, New York

SKIN metastases from carcinoma of the breast may be so disguised as to be mistaken for postoperative inflammatory entities. A group referred to as having erysipelas-like characteristics is seldom identified correctly when first seen. The origin may be in the neighborhood of a mastectomy scar, and is marked by reddening and some edema of the skin, with a flaming, well demarcated, advancing border. Histologically, the skin appears free from pathology except for metastatic permeation of the subpapillary vessels. There is no final agreement as to whether these vessels are capillaries or lymphatics. We have studied two typical cases, both of which were mistaken for postoperative complications. They were treated as such for some months before the correct diagnosis was made. Available biopsy material subjected to serial sectioning clarified some mooted points.

The resemblance of certain metastatic lesions to erysipelas was noted by Unna. It was not until 1924, however, that the condition was given a specific name. Kuettner, describing such a disorder, called it "erysipelas carcinomatosa." He believed the metastatic process involved the superficial blood vessels. In the same year, Lee and Tannenbaum reported 28 cases of what they called "inflammatory carcinoma" of the breast, some of which resembled erysipelas and undoubtedly fall into this group. In spite of the wide variations in the pathological findings of the primary neoplasm, the inflammatory aspect was considered a distinct clinical phase, with diffuse lymphatic metastases as the most manifest pathological feature. Venues, likewise, were thought to be involved. In 1928 Ruder differentiated the condition from Paget's disease by its subepidermal rather than its intra-epidermal metastatic extension. He called the involved channels blood vessels. Rasch in 1931 considered the name "erysipelas carcinomatosa" unfortunate, since the condition is primarily cancerous. He therefore proposed the name "carcinoma erysipelatodes," and differentiated it from cancer encuirasse as

did Kuettner, by its lack of scleroderma-like skin and by its propagation in what he felt were blood vessels. Barber presented a case of Paget's disease which had an erysipelas-like discoloration of the chest wall. The metastatic propagation was thought to be in blood vessels. In 1933 Weber (13) chose the name "telangiectatic carcinoma," because a case noted by him did not resemble erysipelas. Sections taken from a spreading area revealed an enormous dilatation of what were apparently cutaneous capillaries, in which were found cancer cells. Some of the vessels which did not contain red cells might have been lymphatics. Shortly afterward, von Vonno described a similar case as "carcinoma telangiectaticum." Weber (14) believed that the condition deserved a special niche in clinical medicine, and that it could be found in association with Paget's disease or cancer encuirasse. He stated that it spread mainly by way of blood vessels, although lymphatics and tissue spaces could be involved.

On the other hand, Pfahler and Case described the process as extending largely through the lymphatics and only rarely through blood vessels. They had noted and indexed 15 cases as "malignant lymphangitis," but changed the name to "erysipelas carcinomatosa" to conform with those previously reported in the literature. They emphasized the frequency with which it was mistaken for radiodermatitis or radiotelangiectasis. Case discussed the histopathological picture as being similar to that reported in the literature, with the exception that the marked capillary dilatation and predominance of blood vessel invasion were not found. The malignant cells appeared in the lymphatics or tissue spaces. This, he stated, was in agreement with the findings of many investigators, including Fischer, Brackertz, Mandl, Durst, Delbanco, Cemjachowsky, and Bondarcuk (3) who were of the opinion that the tumor cells spread by way of the lymphatics. Rotter studied 4 cases, 1 of which was in a male. After careful histological scrutiny he decided that only lymphatics were involved. Freeman and Lynch described a patient, who, 1 year after surgery for breast malignancy, developed an eruption which might have been mistaken for lymphoheman-

gioma. Few characteristics of erysipelas were present. Microscopically there were unidentified vascular channels crowded with tumor cells. The presence of erythrocytes in some suggested that at least an occasional blood vessel was involved along with the lymphatic vessels. The a thors question whether in the absence of redness, elevation of temperature, and active spreading border

one should call the disorder carcinoma erysipilatodes. When diffuse cutaneous infiltration is an outstanding feature, they prefer the term an epidermal carcinoma. Satenstein recalled a case in which the extension was by both blood vessels and lymphatics. Dawson and Shaw reported bilateral breast neoplasm which extended to distant organs by way of lymphatic and blood es

sels. Dilatation of channels was a prominent feature. They therefore felt justified in describing the disorder as "generalized telangiectatic carcinoma." They suggest that carcinoma erysipelatodes is merely a late stage of malignant mammary tumor with cutaneous carcinomatosis which may in some cases be associated with more typical forms of cancer en cuirasse and Paget's disease of the nipple. They felt there was little justification for regarding this, when accompanied by reddening, a distinct pathological entity as suggested by a specific name.

The great variance in the foregoing reports indicates a need for additional study of the underlying process. Two patients with carcinoma of the breast, who, after operation, presented clinical features suggesting erysipelas, were observed. The skin was studied by repeated biopsy in an effort to clarify some of the pathological features. This material was sectioned serially.

REPORT OF CASES

CASE 1. C. S., a white American female, aged 47 years, entered the Brooklyn Cancer Institute on March 2, 1936, with a chief complaint of an enlarged gland in the right armpit of 1 year's duration. She had had no knowledge of a mass in the breast. Her family and past histories were irrelevant. Physical examination revealed both breasts to be small, with practically no glandular tissue palpable. A 2.5 centimeter nodule, not attached to the skin or chest wall, was palpated above and external to the areola of the right breast. Associated with this were matted glands in the midaxillary and anterior axillary fold on the same

side, approximately 3 times larger than the primary lesion. The glands were freely mobile. No other regional or distant metastases and no inflammatory aspects were noted (Fig 1).

She was given roentgen therapy and the following factors were used: 200 kilovolt, 40 centimeter skin, target distance, 1 millimeter of copper and 1 millimeter aluminum filtration, two 6 by 8 centimeter fields, anterior and lateral ports cross-firing the breast and areola, for a total of 1600 r each. The same factors were used via 1 anterior and 1 posterior 10 by 15 centimeter portal to the axilla for a total of 1600 r to each. Following roentgen therapy, there was marked diminution in the notable pathology

Fig 7 Section of skin lesion from Case 2. Subpapillary channels are slightly distended with masses of tumor cells.

Fig 12 At this magnification a group of tumor cells appear to lie in a blood vessel containing erythrocytes

Eight months previous to admission, she noticed a walnut sized, hard, painless mass in the right breast which grew larger slowly. The skin became involved 6 months after the appearance of the mass.

Physical examination revealed an elevated, round, hard, 4 centimeter mass situated in the upper outer quadrant of the right breast, covered by a red, glossy skin. In the right pectoral border, a 5 centimeter sized indurated, metastasis was found, adherent to the skin. The supraclavicular area was negative (Fig. 5). Laboratory examination including roentgenograms of the chest revealed no evidence of distant metastases. Wassermann was negative. Urine and blood tests showed them to be normal. Specimen obtained by punch biopsy of the breast was reported as carcinoma.

She received a course of pre-operative roentgen therapy between May 31, 1938, and July 13, 1938. The following factors were used: 200 kilovolt, 50 centimeter skin, target distance, 2 millimeters copper and 1 millimeter aluminum filtration, 2 ports cross-firing each of the areas treated, breast ports 10 by 15 centimeters, other ports 8 by 10 centimeters. The breast received 3,000 r to each port with a tumor dose of 3,030 r. The axilla received 2,600 r to each port with a tumor dose of 3,926 r. The right supraclavicular region received 2,400 r to 2 ports with a tumor dose of 3,878 r. A satisfactory radiation reaction was noted on the skin. The breast mass broke through the skin following therapy but this healed following conservative treatment. The mass in the axilla diminished in size and was softer.

On October 1, 1938, a radical mastectomy was performed. Involved glands had to be dissected away from the axillary vein and from the lateral border of the latissimus dorsi. A large skin flap was removed from the breast, necessitating the undermining of the skin toward the midline of the sternum and also at the lateral border of the incision.

Pathology A 4 centimeter mass was present in the upper outer quadrant, adherent to the skin. Several axillary glands appeared to be grossly involved in the neoplastic process. Sections through the mass were composed of an extremely dense, poorly cellular, fibrous tissue within which were numerous small rows of neoplastic cells which for the most part showed no definable cell bodies, and irregular, extremely chromatic nuclei. Vesicular nuclei were rare. Nucleoli and mitoses were absent. There was a very scant lymphocytic infiltrate. Groups of tumor cells

Fig 13 High magnification of tumor cells seen in Figure 12. They are confined to a lymphatic which is surrounded by the branching of a capillary. Arrow points to the single cell thickness of their respective walls. The erythrocytes are confined to the capillary.

which extended into the surrounding fatty tissue showed less change, the nuclei commonly being vesicular. An axillary lymph node was almost completely replaced by tumor tissue which showed a distinct alveolar and some times a pseudoglandular arrangement, the individual cells being prominent, with a pale cytoplasm, vesicular nuclei, and distinctly definable nucleoli. No mitotic figures were noted. No findings of note were present in the sections through the nipple, skin, or underlying large ducts or lobules. There was no involvement of the underlying pectoral muscle. The diagnosis was duct carcinoma of breast, with axillary lymph node metastases, marked radiation changes in the breast mass.

The wound healed uneventfully except for a small triangular area at its center, which was treated with azochloramide solution and later with cod liver oil ointment. One month after operation, marked erythema was noted extending medially from the wound. The patient stated that the reddening followed wet dressings of azochloramide. The redness was therefore attributed to this. This dermatitis apparently subsided somewhat following discontinua-

Fig 14 The distention of the tumor bearing lymphatic has interfered with the nutrition of the overlying epidermis with resultant atrophy.

Fig. 9.

Fig.

Fig.

Fig. 9. Case 2, 3 months after mastectomy. The process on the opposite breast had developed into typical carcinoma erysipelatodes. Not the flaming, well demarcated border.

Fig. 10. Photograph taken with patient in same position

The lump in the upper outer quadrant of the right breast could not be palpated. A residual gland was still felt in the apex of the axilla. For sociologic reasons the patient delayed the proposed mastectomy. Aside from microcytic hypochromic anemia, her laboratory work up, as negative. The Wasserman and blood chemistries were normal.

Eleven months after admission, a nontoxic nodular goiter as removed. On March, 1937, year after completion of roentgen therapy, radical mastectomy as done.

Pathology. The specimen consisted of right breast, the underlying pectoral muscles, and axillary tissues. Extensive sectioning through the mammary parenchyma showed no gross evidence of neoplastic lesion. However the axillary tissue presented numerous discrete, firm, white, nodular areas, apparently lymph nodes, which grossly appeared to be completely replaced by neoplastic tissue. Sections through the skin showed no abnormal findings. In numerous sections throughout the breast the large ducts showed no alteration of the lining epithelium whether proliferative or neoplastic. The majority of parenchymal lobules also showed no pathological findings of note. Toward the outer upper quadrant, however, are many lobules which showed marked increase in fairly dense fibrous tissue, both perlobular and periductal. Here there as considerable hyperplasia and proliferation of the lining cells of the small ducts, and in an occasional lobule some of these proliferating cells appeared distinctly atypical. The neoplastic cells are found in small sheets. They are large, with ill defined borders, pale pink or clear cytoplasm, and round nuclear nuclei with single nucleoli. A scattered perivascular lymphocytic infiltrate was found. Toward the axilla were collections of lymphoid tissue, some definitely small nodes. Several contained metastatic masses of neoplastic cells both in dilated peribubular spaces and invading the periphery of the node. One had been completely replaced by tumor tissue. The fibrosis in the surrounding tissue as all marked here. It was fairly dense but not of the keloid type. Within the lumen of one large vessel, apparently vein, as mass of tumor cells.

The diagnosis as carcinoma of the right breast, with villous lymph node metastases. The cell type suggested duct origin. The proliferation of the duct epithelium is points typical, with the fibrosis, suggested fibro-adenomatous origin. The malignancy was judged Grade 3.

After operation the patient received 300 milligram hours of radium via drabs in the operat and Her

as in Figure 8, showing advance of lesion during 3 weeks.

Fig. Case 2, just 1 year after operation. The process had spread from the right mastectomy scar, across the anterior chest wall, and past the left axilla to the angle of the scapula.

general condition was good but persistent sinus remained (the upper angle of the wound). The skin about the sinus became red and tender, this improved somewhat as drainage progressed. Cultures from the chest wall and sinus revealed hemolytic streptococcus, staphylococcus aureus and staphylococcus epidermidis.

Five months after the operation, the surgeon noted that the wound was completely healed except for tiny draining sinus at the apex. The reddening of the skin surrounding this area as attributed to inflammation. Two months later this redness as interpreted as postoperative eczema. Subject's symptoms varied from slight itching to severe burning. Right supraclavicular glands were felt to this time and were treated with deep therapy. A year after the operation, the redness had spread to the posterior axillary line and as diagnosed as rhabdomyoma. Shortly afterward, it as thought to be an eczematous lesion, possibly predicated by fungus infection. Later, she as given bland ointments to apply to the reddened area. Ten years after the operation, the skin condition as thought to be due to the self application of medication. Finally however her condition as recognized as true skin metastases. At this time, the skin presented flaming red, clearly marginated, diffuse eruption which spread in all directions from the right mastectomy scar. The lesion had spread to involve the opposite breast, downward over the abdomen almost to the umbilicus, and posteriorly on to the back and shoulders, almost to the midline (Fig 4). Biopsy of the skin showed it to be covered with thin, otherwise normal, epithelium. The rete pegs and papillary cores were well preserved. An occasional, thin, dilated channel contained neoplastic cells with hyperchromatic angular nuclei (Figs 3 and 4). This confirmed the clinical impression of malignant involvement of the skin.

The patient refused medical care and returned home where she died August, 1939, 3 1/2 years following her entrance to our clinic.

Case 2. B. S. white American female aged 43 years, entered the Brooklyn Cancer Institute on May 7, 1934, complaining of a lump in the right breast of 8 months duration. Her family history as irrelevant. Eighteen years previously lactocelia, which occurred after childbirth, as removed. Two years later after another delivery she developed multiple abscesses in the left breast, one of which was incised. Following this, the patient nursed her child on both breasts for 1 year.

siderable time elapsed between their appearance and recognition. Both were mistaken for postoperative inflammation, dermatitis venenata, fungus infection, and radiodermatitis. The medicolegal implication of the last diagnosis is significant. The diagnostic confusion could be readily obviated by prompt biopsy of any obscure lesion.

The pathological evidence would seem to indicate that the involved vessels are lymphatics. The channels containing tumor cells did not contain erythrocytes. Conversely vessels containing erythrocytes were demonstrated to be discrete from those containing tumor cells. It is conceivable that the close proximity of blood vessels to the permeated lymphatics might make them vulnerable to metastatic invasion, but we did not note this. The previously reported cases differed as to the amount of lymphatic dilatation. Serial sectioning clarified the differences by revealing the dilatation to vary between wide limits, depending upon the section examined.

Successive sections showed the lymphatics to be free from tumor cells for short distances. This raises the question of method of metastatic spread. Might this indicate that the spread was by embolization rather than permeation? This does not seem likely. The empty spaces appear to represent breaks in the advancing stalk rather than gaps between emboli. Clinically, the appearance of a well demarcated, slowly advancing and spreading lesion speaks for a steady outgrowth by permeation rather than an erratic spread by embolization. Absence of early distant metastases is indirect evidence pointing to same conclusion.

The condition appears to have sufficiently distinctive physical and pathological characteristics to warrant giving it a separate place in clinical medicine. Names implying an acute process are unfortunate. While the cases often present the startling appearance of an acute lesion, they are in fact chronic. The well demarcated, reddened, and advancing border is the only common factor with erysipelas. We would favor a pathological term implying a diffuse subepidermal carcinomatosis from carcinoma of the breast, but we believe that the addition of still another name could only add to the confusion. The term "carcinoma erysipelatodes" is sufficiently descriptive to identify the condition.

It would be of extreme importance to understand the factors responsible for making a given tumor react in a particular way, such as these two tumors have done. To venture any such explana-

tion with the information at hand would be imprudent indeed. The problem, however, should be stated for future investigation.

SUMMARY

1 Two typical cases of carcinoma erysipelatodes which developed in postoperative mastectomy patients are presented.

2 Both were mistaken for postoperative inflammatory complications, dermatitis venenata, fungus infection, and radiodermatitis. The medicolegal importance of this is significant. The appearance of any peculiar skin lesion following mastectomy for malignancy should be regarded with suspicion and biopsy examination made.

3 The pathological material from repeated skin biopsies was studied by serial sectioning.

4 It appears that the metastatic process, in the cases observed, is one of permeation of the subepidermal lymphatics and tissue spaces, rather than venous channels.

tion of aureochloride and application of blood ointment. Subject's symptoms consisted of moderate itching and burning. 7 months later note was made that pigmentation present on the chest all as due to radiation. Questionable small nodules were felt in the skin. It is to be noted at this time that the patient had received no post-operative radiation therapy and that any skin which might have been pigmented from pre-operative therapy had been removed at operation.

7 months later (5 months after operation) her skin condition was finally recognized as carcinoma, erysipelas. At this time, semicircular scar approximately centimeters in length, as noted on the right chest wall at the site of mastectomy. From its mid point, an 8 centimeter linear scar extended transversely toward the sternum. A brownish red well demarcated discoloration of the skin, with flaming border, extended medially from the lower half of the scar for distance of centimeters. The skin was slightly brown and indurated. No nodulation was demonstrable. The entire area was slightly raised (Fig. 6).

Biopsy specimens from the middle and edge of the lesion, as indicated on the photograph, revealed diffuse carcinomatous involvement of the subpapillary channels (Fig. 7). Cultures from the surface of both involved and uninvolved skin showed growth of hemolytic *Staphylococcus aureus*. The results given course of medical therapy following which there was remarkable clinical subsidence of the process. However in June, 1939, similar diffuse, red mottling was noted over the other breast (Fig. 8). Three weeks later the appearance was typical of carcinoma, erysipelas. The skin over the entire breast was bright red, with well demarcated, flaming edges (Figs. 9 and 10). Repeated biopsies confirmed the clinical impression. Intravenous deep therapy cross-firing large area, was instituted in an effort to stem the advance. Though good local response was obtained, the process continued its formidable spread. Three and half months later the flaming edge had extended posteriorly to the angle of the scapula (Fig. 11), inferiorly over the abdomen, and superiorly toward the clavicles. Roentgenograms of the chest and osseous system were negative for metastases. The right supraclavicular nodes appeared enlarged on the roentgenogram. The leucocyte count varied from 7,000 to 9,000 with 68 to 8 per cent polymorphonuclear cells.

It is remarkable that until this time constitutional symptoms were absent. Indeed, the patient felt well enough to supplement her meager income by taking in sewing. Finally in December, 1939, 26 months after her first complaint and about 18 months after skin involvement, the latter became so severe as to necessitate hospitalization. Multiple nodules and ulcerations were present over the anterior chest wall. The skin was brown and indurated.

With right supraclavicular and arm edema. But even at this time the periphery of the lesion resembled erysipelas enough to cause new surgical service to prescribe sulfanilamide. This, of course, as discontinued because the nature of the lesion, as reaffirmed by biopsy.

The patient went slowly downhill, developed jaundice, possibly due to abdominal metastases, and expired April 8, 1940, 30 months after her first complaint, and 16 months after skin involvement. Autopsy could not be obtained.

The random histologic sections of skin first studied revealed slightly dilated subpapillary channels filled with tumor cells. The uncertainty encountered in the literature as to whether they were lymphatics or capillaries still existed. In the normal skin the easily recognized subpapillary

capillary plexus and the more obscure lymphatic plexus lie in close proximity. The lymphatics are usually collapsed, resemble tissue spaces, and are nearly unrecognizable unless they contain cellular elements. When found dilated they are often mistaken for capillaries. The vascular channels in question lay so close to both these plexuses that they might have been taken for either. They were lined with single layer of endothelial cells and surrounded by a sparse infiltrate of lymphocytes. It was decided to subject the biopsy material to serial sectioning in an attempt to determine their true identity. More than 300 sections were studied.

Barring artefaction, the presence of an erythrocyte in a vessel might be taken as evidence that it was a capillary or venule. In the sections studied, no erythrocytes were found in the vessels containing tumor cells. It was assumed therefore that they were lymphatics.

In some sections the proximity of the lymphatics and capillaries were so close that the tumor masses appeared to lie in vessels containing erythrocytes. Closer scrutiny, however, always revealed the erythrocytes to be confined to capillaries which were discrete from the involved lymphatics. Occasional sections showed a capillary containing red blood cells separated from a tumor bearing lymphatic by only the single cell thickness of their respective walls. Figure 12 shows such a section where a small tumor mass appears to lie in a venule. Higher magnification reveals the tumor mass to be confined to a lymphatic which is separated from the vessel containing erythrocytes by only the single layer of cells of their respective walls (Fig. 13). In all the sections the lymphatics maintained their discrete identity in their expected anatomical location.

In some areas the proximity of the different vessels led to compression of the capillaries by distended lymphatics with resultant atrophy of the overlying epidermis (Fig. 14). Further growth of such a lesion might well lead to nodular elevation of the skin.

Serial sectioning revealed the amount of lymphatic dilatation to vary between wide limits. Single sections gave the picture at either extreme. Indeed, in an occasional section the lymphatics were so narrow as to hold only a single tumor cell. In some instances the involved lymphatics were free from tumor cells for short distances.

The metastatic process was by no means confined to the subpapillary lymphatics but involved the tissue spaces and subcutaneous tissue.

The cases are of clinical interest because of the difficulty encountered in their diagnosis. Con-

siderable time elapsed between their appearance and recognition. Both were mistaken for postoperative inflammation, dermatitis venenata, fungus infection, and radiodermatitis. The medicolegal implication of the last diagnosis is significant. The diagnostic confusion could be readily obviated by prompt biopsy of any obscure lesion.

The pathological evidence would seem to indicate that the involved vessels are lymphatics. The channels containing tumor cells did not contain erythrocytes. Conversely vessels containing erythrocytes were demonstrated to be discrete from those containing tumor cells. It is conceivable that the close proximity of blood vessels to the permeated lymphatics might make them vulnerable to metastatic invasion, but we did not note this. The previously reported cases differed as to the amount of lymphatic dilatation. Serial sectioning clarified the differences by revealing the dilatation to vary between wide limits, depending upon the section examined.

Successive sections showed the lymphatics to be free from tumor cells for short distances. This raises the question of method of metastatic spread. Might this indicate that the spread was by embolization rather than permeation? This does not seem likely. The empty spaces appear to represent breaks in the advancing stalk rather than gaps between emboli. Clinically, the appearance of a well demarcated, slowly advancing and spreading lesion speaks for a steady outgrowth by permeation rather than an erratic spread by embolization. Absence of early distant metastases is indirect evidence pointing to same conclusion.

The condition appears to have sufficiently distinctive physical and pathological characteristics to warrant giving it a separate place in clinical medicine. Names implying an acute process are unfortunate. While the cases often present the startling appearance of an acute lesion, they are in fact chronic. The well demarcated, reddened, and advancing border is the only common factor with erysipelas. We would favor a pathological term implying a diffuse subepidermal carcinomatosis from carcinoma of the breast, but we believe that the addition of still another name could only add to the confusion. The term "carcinoma erysipelatodes" is sufficiently descriptive to identify the condition.

It would be of extreme importance to understand the factors responsible for making a given tumor react in a particular way, such as these two tumors have done. To venture any such explanation

with the information at hand would be imprudent indeed. The problem, however, should be stated for future investigation.

TRANSURETHRAL PROSTATECTOMY

A Photographic Record of the Operation of Transurethral Resection

FLETCHER H. COLBY M.D. F.A.C.S. and HOWARD I. SUBY M.D. Boston, Massachusetts

ILLUSTRATION is an effective method of description. With advances in photographic technique pictures are taking an increasingly important place in medical writings. Operative procedures which require the use of telescopes and lens systems have fields of vision often limited to the operator alone. It is not easy for an untrained person to understand these operations, and restricted vision makes teaching difficult. Operations of this sort are more easily portrayed by illustration than description. Therefore, we have used recent improvements in photography to illustrate the operation of transurethral prostatectomy.

Fig. 1. Low spinal anesthesia. Safe, satisfactory anesthesia is obtained with 50 milligrams of novocain crystals in the fourth lumbar interspace with the patient in the sitting position.

This communication describes graphically the method employed by us for the transurethral removal of the prostate gland. The illustrations are actual photographs of the hypertrophied gland, the changes which result from obstruction, and transurethral removal of the prostate, taken with a cystoscopic camera during operation. The sharpness of the photographs is an evidence of the clear vision obtainable with modern instruments and so necessary for a successful operation.

Careful preliminary studies of patients with prostatic obstruction must be made. We feel, however, that manipulations should be as few as possible and that even catheterization is apt to be dangerous. Cystoscopic examination has led to complications so often in the past that we prefer to eliminate this procedure if possible. Cysto-urethrograms () we believe, give a more accurate estimation of the size of the obstructing prostate and its suitability for transurethral removal than cystoscopic examination consequently cystoscopy with its danger and discomfort often can be eliminated. Prostates enlarged beyond a certain size obviously are best removed by open operation, preferably perineal prostatectomy. Others similarly are suited to transurethral removal. When decision is difficult cysto-urethrograms are helpful.

This is our usual pre-operative preparation of patients who have prostatic obstruction. General physical examination is done and includes complete blood counts, non protein nitrogen, blood sugar and Wassermann tests. Intravenous pyelograms are made these provide a test of renal function and afford information regarding the spine and pelvis, contour of the bladder and give a fair estimate of residual urine. Patients in acute retention those with large amounts of residual urine or with poor renal function are put on constant drainage with a Foley retention catheter. Retention catheters are immediately connected to sterile closed drainage system and irrigated as necessary with sterile boric acid solution. If the non protein nitrogen is normal, renal function adequate, the general condition of the patient good and the prostate only moderately enlarged by rectal examination, operation is considered safe without further study. Patients with

Fig 2 Preparation for operation Good exposure and complete sterility are provided Patient is in position on McDevitt-Alcock table

a history of hematuria or those with any filling defect of the bladder suggestive of tumor are examined with a cystoscope Responsibility for such complications as diabetes, cardiac disease, or others, is shared with a medical consultant We consider pre-operative chemotherapy important

Low spinal anesthesia for transurethral resection has been used by us for several years with such good results that it is now employed whenever possible This method of anesthesia amounts almost to a regional anesthetic and its level goes little higher than the symphysis pubis It has resulted in no significant falls in blood pressure and usually lasts for about one hour One hundred milligrams of novocain crystals in 2 cubic centimeters of spinal fluid is injected into the fourth lumbar interspace with the patient in the sitting position (Fig 1) The patient is kept in this position for 3 minutes after the injection This technique was described by Nesbit (2) in 1936 No complications attributable to anesthesia have resulted since its adoption

Increased comfort to the patient and better position for operating have been secured since we have used the McDevitt-Alcock table (Fig 2) Patients are as carefully prepared as for any operation and the operator wears a sterile gown and gloves

A definite routine makes for thoroughness, so examination and operation are conducted in definite sequence The bakelite sheath of the Mc-

Carthy resectoscope with Timberlake obturator is passed to the bladder and a specimen of urine is taken for culture Both the No 28 and 24 instruments are at hand since male urethras vary in size and some will not accommodate the larger sheath The bladder is carefully examined with the 90 degree observation telescope which provides a large clear field of vision The photographs demonstrate that intravesical protrusions of the enlarged prostate (Figs 6-9) and changes produced from obstruction, such as trabeculation and diverticula (Figs 3-5), are clearly discernible Further examination with the retrograde telescope, which looks toward the operator, visualizes the trigone, ureteral orifices, and internal urethral orifice (Fig 10) By replacing the retrograde telescope with the foroblique lens system, attached to the working element of the resectoscope, those portions of the prostate which encroach upon the urethral lumen are seen (Figs 11-12) The extent and variety of obstruction is thus clearly defined and operation may be started

Operation, as examination, follows a definite course The upper portions of both lateral lobes are first removed (Fig 13) These cuts are made at about eleven and one o'clock Projecting tissue at the anterior commissure is then resected Deep cuts are now made in the lower portions of the lateral lobes where they join the median lobe (Fig 14) Bleeding frequently is profuse in these areas since much of the blood supply to the lateral and median lobes is cut across A resectoscope

Fig 14 Deep cut in lateral lobe Repeated cuts remove the enlarged prostate layer by layer

Fig 15 Remains of median lobe A thin rim of hypertrophied prostate remains on urethral floor

Fig 16 Operation completed Obstructing tissue removed Clear view into bladder Note smooth fibrotic appearance of prostatic capsule

employs two types of current regulated by a foot switch The cutting current removes tissue, and the coagulating current is used to stop bleeding points With the bleeding of this very vascular region controlled, remaining tissue is removed with little hemorrhage Intravesical protrusions of the lateral lobes are cut away until the muscular fibers of the internal sphincter appear The striated appearance of this muscle is an important landmark which makes it plainly evident that the cuts are sufficiently deep Removal of the intravesical part of the middle lobe is simple and quickly accomplished The intra-urethral parts of the prostate are now left The lateral lobes are hollowed out layer by layer down to the verumontanum which is generally an easily seen landmark (Fig 12) Remaining tissue to be removed are the remnants of the lateral lobes and the remains of the median lobe on the floor of the urethra (Fig 15) In our experience this is removed most effectively with the Nesbit modification of the McCarthy resectoscope With a finger in the rectum remaining nodules of hyperplastic tissue are readily engaged in the loop electrode and cut away until all hypertrophied tissue is removed The rectal finger guards against cutting too deeply and avoids undue pressure of the sheath against the urethra The differentiation between normal and hypertrophied prostatic tissue is usually clear Hyperplastic tissue has a characteristic structureless frosty appearance in contrast to the gray orderly structure of the normal prostate Enlarged glands, within one's ability to resect, are thus cleanly and systematically removed (Fig 16) Cut tissue falls back into the bladder and is removed by evacuation only as is necessary for clear vision At the conclusion of the operation

bleeding points are controlled by coagulation, and a 30 cubic centimeter Foley type catheter is inserted into the bladder Tension on the bag for hemostasis is seldom necessary

Postoperative care is usually simple Catheters are connected immediately to a sterile closed drainage system and irrigated frequently enough with sterile boric acid solution to prevent clotting Sedatives and intravenous fluids are given as necessary Catheters are removed in from 3 to 5 days after operation After this the great danger of infection makes it unwise to catheterize these patients Curiosity regarding residual urine should be restrained Difficult urination or persistently cloudy urine means incomplete removal of the hypertrophied prostate and indicates the necessity of further operation The average postoperative stay in the hospital has been about 10 days

The accompanying photographs illustrate many of the steps in the transurethral removal of the prostate They demonstrate that clear and adequate vision may be obtained during operation and that those prostates suited to resection are cleanly and effectively removed by this method

SUMMARY

The management of the obstructing prostate and its removal by transurethral resection is described and illustrated by photographs taken at operation with a cystoscopic camera

FREE BONE FLAP OSTEOPLASTIC CRANIOTOMY

EDWIN BOLDREY M.D. San Francisco California

WILLIAM CONE, M.D. Montreal, Canada

THE orthodox method of osteoplastic craniotomy is to leave the bone flap attached to muscle, as was begun by Wagner 1880, 50 years ago.

In 1936 one of us (W. V. C.) commenced the use of free bone flap osteoplastic craniotomy in selected cases. The chief reason for desiring a change was that there are so many areas of the skull where muscle attachment necessitates a larger scalp and bone flap than would otherwise be required for an adequate approach to the underlying intracranial disease. Other advantages have appeared and the results have been so uniformly satisfactory that the free bone flap has been turned in an increasing percentage of operations, so that at the present time we have available over 50 cases in which the procedure was used and from which conclusions may be drawn.

The procedure is not an original one. Lencze, 1933, reports that he has completely freed the skull flap in about 30 osteoplastic craniotomies since 1919. O. Sjöqvist, in a personal communication states that he has used the method several times. Doubtless many others have employed it. This report is indicated, however, because the procedure is not yet widely recognized, because it is feared by many of those acquainted with it, and because we feel that its advantages should be brought again to the attention of those surgeons who operate on patients with intracranial disease.

PROCEDURE

The exact localization of the lesion having been made, the scalp flap is planned in the usual manner. After hemostasis has been established along the incision line, the scalp is reflected with the raspatory, the line of cleavage being between the bone and the pericranium. It is important that the pericranium be attached to the scalp, retaining its intact blood supply because of its important rôle in bony repair. We feel that it is this osteoplastic membrane that requires nourishment—not the bone already laid down. When this scalp flap is completely turned back and all bleeding is controlled, it is wrapped in gauze moistened with Ringer's solution, is padded to prevent kinking,

and is held retracted by means of barbed fish hooks which are attached to rubber bands which in turn are attached to the adjacent drapes with Allis forceps.

Four to six burr holes are drilled at proper positions and the flap is cut out with the Gigli saw, care being taken to stagger and bevel the sawed line as described by Stookey 1937, so that the flap will interlock and be stable when replaced. Before the flap is freed, marks are made indicating the position of the punch holes for wiring the flap at the end of the operation. When the last attachment of the bone flap is being cut, extreme caution must be employed to prevent the flap being suddenly detached from the dura and dropped to the floor. When completely severed, it is dissected from the dura in the usual way (usually it lifts off with surprising ease) is wrapped in a dressing moistened with Ringer's solution, and is left on the nurse table until needed at the close of the procedure.

We have found that manipulation is avoided and time is saved if the holes for wire are introduced before the flap is laid aside in the beginning. Two or three points for wiring have proved to be sufficient. Number twenty-eight chromium steel wire is used, is tied or twisted, and the knot or twist turned into the outer hole. There is no essential change in the closure of the aponeurosis and skin.

Our patients who have had free bone flap osteoplastic craniotomies have ranged in age from 3 to 61 years. They have been equally divided as to sex. The majority have been operated on because of intracranial tumor. All areas of the convexity of the calvaria have been reflected. Because of the nature of their disease, many patients have died within a few months. However 3 patients were followed for 2 years; 1 of these patients is still living.

By way of complication, a patient developed an infection as a result of skin sensitivity to boric acid. The bone flap became involved, necessitating removal. This bone flap was a small one and was sacrificed at once without too great deformity. Had the standard larger sized attached flap been used, it too would have had to be sacrificed and a much greater deformity would

From McGill University and the Montreal Neurological Institute.

Fig 1, left Case 1 Roentgenogram showing free bone flap 6 days after operation

Fig 2 Free bone flap 5 months after operation Com-

parison of radiopacity of flap with that of the rest of skull and with appearance immediately after operation shows no absorption There is evidence of bony union

have resulted One flap was dropped on the floor during the operation It was washed with Ringer's solution, and was boiled for 10 minutes in the same solution Thus far, this has produced no demonstrable ill effect, and the flap is still satisfactory However, there has been an elapse of only 3 months

there has been evidence of transitory decalcification in some instances

The results of roentgen-ray studies of these patients with free bone flap osteoplastic craniotomies likewise have been satisfactory The following brief case reports are included as objective evidence

Large doses of roentgen-ray have been directed through the flap to underlying tumors on many occasions, the treatment commencing as early as the fifth postoperative day No deleterious effect has been seen following such treatment, though

CASE 1 E S, female, aged 10 years On August 18, 1939, a left osteoplastic craniotomy (free bone flap) was turned and a subtotal removal of a large intracranial neoplasm carried out Figure 1, is a roentgenogram showing the bone flap on August 24, 1939 She returned on January

Fig 3, left Case 2 Roentgenogram 2 days after operation showing condition of free bone flap

Fig 4 Free bone flap 11 months after operation, 5,700

r units of roentgen therapy have passed through a port centering in this region There is some evidence of central rarefaction but there is also bony union with the skull

Fig. 5. left. Case 3. Roentgenogram with flap side away from film, taken 45 days after operation.

Fig. 6. Case 3. Roentgenogram with flap side next to film. This ray film was taken 18 months after operation. Note the bony union and definite lack of evidence of absorption.

0, 030 with signs of recurrence of the tumor. On that date, the roentgenogram (Fig. 5) suggests that bony union between the skull and the flap has occurred extensively. There is no evidence of absorption of bony substance in the flap.

CASE 2. M. W. female, aged 47 years. On July 7, 035, left parietal free bone flap osteoplastic craniotomy was carried out for the relief of symptoms produced by cystic glioblastoma multiforme. On July 9, 035, the roentgen-ray appearance was that seen in Figure 3. In the ensuing months, she received roentgen therapy totalling 8,500 milis, 5,700 of which were passed through port centering over this bone flap. In February, 039, roentgenograms showed some resorption: the center of the bone flap but there was bony union at the edges. On June 26, 039 there was less resorption than was found in February (Fig. 4) and bony union. The skull was more so evidence. The patient has since died. Autopsy not obtained.

CASE 3. H. McD. male, aged 6 years. On April 12, 038, right frontal free bone flap osteoplastic craniotomy as performed and postoperative postencephalic cavitation drained. On April 6, 038, roentgen ray films (with the left side of the head down) (Fig. 5) were taken. The patient's course has been without incident. He is our oldest patient and has one of the longest postoperative courses in our series. Figure 6 shows the appearance of the skull flap on January 6, 040. There is bony union between the flap and the skull. There is no resorption of bone, in fact there may be some increased density.

of operative treatment of severe head injuries. In all of these situations it has been shown that the preservation and union of bone is accomplished only if the bone is freshly removed from the patient's own body and if the attachment of the periosteum to the surrounding tissues is maintained.

Bolled autopsy bone, in our experience and that of others, is absorbed within 18 months (Gurdjian, 035). In the case of our patient whose contaminated flap was bolled, insufficient time has elapsed to enable us to submit a report on the fate of the bone. Naffziger 035, however has noted absorption within 8 months under similar circumstances.

The advantages to be gained by freeing the bone flap in osteoplastic craniotomy are many. Only that bone, the removal of which is necessary to visualize the intracranial lesion, has been elevated. The absence of an overhanging ledge gives greater freedom of action to all members of the operating team. The tendency for the procedure to fall into successive stages without overlap, plus the reduced flap size, facilitate speed in turning the flap and cut down blood loss. The shock almost always attending the coarse operative manipulation of cracking up the flap is avoided. Oozing of blood from the bone flap during and after operation is completely eliminated. We feel that trauma to the soft tissues is considerably less. The craniotomy can be enlarged by removing adjacent skull as an auxiliary flap, without leaving a skull defect. A decompression can be made in the usual way if desired.

It has long been obvious that bone cut free from all attachment will live if replaced in a suitable environment. We have had repeated occasion to observe the good results clinically and roentgenographically of tibial, ilial and rib grafts in the repair of old skull defects as well as elsewhere in the body. That skull bone should survive equally well has been proved in many instances in which comminuted pieces of calvaria have been temporarily removed and then replaced in the course

SUMMARY

Free bone flap osteoplastic craniotomy is followed by wound healing that compares favorably with that observed when bone-muscle attachment is retained. Advantages to be gained are the reduced size of the scalp and bone flap usually required, reduced blood loss, reduced soft tissue trauma, increased freedom of action to all members of the operating team, increased speed in turning the flap, and elimination of the danger of hemorrhage due to blood oozing from the bone flap.

THE MANAGEMENT OF THE APPENDICEAL STUMP

Inversion without Ligation of the Stump

LOUIE FELGER, M.D. F.A.C.S., Los Angeles, California

THREE basic methods are generally employed in treating the appendiceal stump. These are (1) simple ligation of the stump, (2) ligation and inversion of the appendiceal stump, and (3) inversion without ligation of the stump. Each of these procedures has its firm adherents and opponents. Each has been equally commended and condemned.

Because of the possibility of the inflammatory reaction about the stump extending to the cecum, intramural abscesses are not unlikely

Fig. 1

Fig. 1. The cecum is delivered into the wound and held by the assistant with moist sponge. The meso-appendix is then transected between clamps and ligated with plain No. 1 catgut.

Fig. 2 and 3. The peritoneal cavity is eff walled off with sponges and then the appendix is amputated at its base between Kocher clamps. 3. The cecum is protected with gauze sponge around the clamp and the stump of the appendix is treated with phenol and alcohol.

Fig. 2.

Fig. 3.

Fig. 3. A Cushing right angle stitch using chromic No. 1 suture on straight swaged needle is applied over the clamp. The end of this suture A is left long. The appendiceal artery not shown in this figure, is caught in this suture. and 2. The clamp is then withdrawn and the suture drawn taut. Using the same suture, continuous Lambert stitch B is applied over the first suture line in the opposite direction to the first layer. 4. The suture B is then tied to the beginning of the first layer A.

The objections raised to the method of simply ligating the stump with no attempt at inversion are (1) it permits contaminated raw surface to remain free in the peritoneal cavity, (2) it violates the sound principle of serosa to serosa apposition in gastro-intestinal surgery and (3) cases of peritonitis and fecal fistulas due to loosening of the ligature or necrosis of the stump are not infrequently reported.

There are also certain objections inherent in the method of ligation and inversion of the appendiceal stump. In this procedure an infected stump is inverted into a closed cavity—the cecal wall.

From the Department of Surgery Cedars of Lebanon Hospital, Los Angeles, California.

We have found the ideal procedure in the management of the appendiceal stump to be inversion without ligation as opposed to simple ligation or ligation and inversion. This method is sound surgically for it approximates serosa to serosa, and inverts the crushed stump into the lumen of the cecum where drainage is adequate. It thus obviates the objections inherent in the two other methods.

In the accompanying figures together with the explanatory legends we present a method of inverting the unligated appendiceal stump. This procedure is advanced not as a new technique, but rather for the sake of emphasis. To date it has been employed successfully in well over 700 cases.

SUPERFICIAL INFECTIONS DUE TO ANAEROBIC STREPTOCOCCI

Indications for Zinc Peroxide Treatment

JACOB REICHER, M D , Dayton, Ohio

INITIATED by the brilliant work of Meleney and his associates, a group of uncommon, chronic ulcers has received an etiological and therapeutic elucidation which appears to have furnished medical science with a new disease and a relatively new weapon, zinc peroxide. The discoverer of this entity has given it the descriptive term "chronic, ulcerative, burrowing, non-gangrenous ulcer due to micro-aerophilic hemolytic streptococci."

Meleney emphasizes both the anaerobic and hemolytic character of the organism as well as either or both undermining and burrowing features of the ulceration. While the writer bows to Meleney's far greater experience and probably superior judgment in the description and treatment of this disease, certain features stand out in the character of 3 of 4 cases here reported as perhaps to warrant some modification in certain concepts. In 2 cases the initial infections were seen, not as ulcerations, but as a diffuse cellulitis in one and an abscess in the other. On the one hand, however, both were caused by a non-hemolytic anaerobic streptococcus, but on the other, the larger of the two assumed the character of an ulceration with burrowing and undermining features so pronounced as to warrant inclusion in this group of infections. Furthermore its response to specific zinc peroxide therapy was so spectacular as to add to the justification for its inclusion. This is described as Case 2 and is illustrated in Figures 5 to 9. The second of these 2 cases (Case 3) revealed no undermining or burrowing propensities but the only organism isolated was an anaerobic non-hemolytic streptococcus, no organism was present on the aerobic media. It is by no means typical of the group, clinically or etiologically, but is included in this report to illustrate the facts that an anaerobic streptococcus may invade without causing burrowing or undermining, and in the absence of these changes can be successfully attacked with non-oxygen-producing antiseptics. Sulfanilamide was used for a short period.

The third of this somewhat unorthodox group (Case 4) is one in which an anaerobic hemolytic

streptococcus was present in some profusion and also demonstrates that in milder cases oxygen production is not an essential requirement in the therapeutic agent. A small sinus communicating with the ulcer represented the only possible tendency to burrow. Despite the use of only mild local non-oxygen-producing antiseptics the sinus did not increase in extent. Undermining was not present. As in Case 3 sulfanilamide was used for a few days.

In his reports Meleney discusses the clinical picture and treatment of some 40 cases, 18 of which were given combined zinc peroxide and intensive sulfanilamide therapy (11). Since the publications of his descriptions eighteen cases have been added by others (1, 2, 4, 6, 7, 14, 15, 16, 17). Some of these (2 and 6), however, do not fit precisely into Meleney's criteria for the establishment of the diagnosis. The writer has had some detailed experience with 2 others, 1 of which (Case 2) as previously noted perhaps should not be included inasmuch as the causative agent was a non-hemolytic rather than a hemolytic streptococcus.

Conversely, in the 2 other infections here reported an anaerobic streptococcus was apparently either the sole or predominating invader, but with virtually complete absence of burrowing or undermining propensities in both. In one of these cases the infectious process due to a non-hemolytic organism progressed to complete healing with antiseptics simpler in character than that used for the undermining or burrowing type. Local antiseptics and, for a brief period, sulfanilamide were used effectively for the other caused by a hemolytic anaerobic streptococcus. Because these infections lacked the gross features Meleney describes they have not been included in this report as a particular variety of chronic ulceration.

The writer does not propose to offer an exhaustive summary of Meleney's laboratory, clinical, and therapeutic studies. These are, by this time, well known to all who are familiar with current literature. They are described in at least one popular textbook (5). It is one of the chief purposes of this paper to emphasize the desirability

THE MANAGEMENT OF THE APPENDICEAL STUMP

Inversion without Ligation of the Stump

LOUIE FELGER, M.D. F.A.C.S., Los Angeles, California

THREE basic methods are generally employed in treating the appendiceal stump. These are (1) simple ligation of the stump, (2) ligation and inversion of the appendiceal stump and (3) inversion without ligation of the stump. Each of these procedures has its firm adherents and opponents. Each has been equally commended and condemned.

Because of the possibility of the inflammatory reaction about the stump extending to the cecum, intramural abscesses are not unlikely

Fig. 1

Fig. 1. The cecum is delivered into the wound and held by the assistant with moist sponge. The meso-appendix is then transected between clamps and ligated with plain No. 10 catgut.

Fig. 2. and 3. The peritoneal cavity is all filled off with sponges and then the appendix is amputated at its base between Kocher clamps. 3. The cecum is protected with gauze sponges around the clamp and the stump of the appendix is treated with phenol and alcohol.

Fig. 2.

Fig. 3.

SUPERFICIAL INFECTIONS DUE TO ANAEROBIC STREPTOCOCCI

Indications for Zinc Peroxide Treatment

JACOB REICHER, M D, Dayton, Ohio

INITIATED by the brilliant work of Meleney and his associates, a group of uncommon, chronic ulcers has received an etiological and therapeutic elucidation which appears to have furnished medical science with a new disease and a relatively new weapon, zinc peroxide. The discoverer of this entity has given it the descriptive term "chronic, ulcerative, burrowing, non-gangrenous ulcer due to micro-aerophilic hemolytic streptococci."

Meleney emphasizes both the anaerobic and hemolytic character of the organism as well as either or both undermining and burrowing features of the ulceration. While the writer bows to Meleney's far greater experience and probably superior judgment in the description and treatment of this disease, certain features stand out in the character of 3 of 4 cases here reported as perhaps to warrant some modification in certain concepts. In 2 cases the initial infections were seen, not as ulcerations, but as a diffuse cellulitis in one and an abscess in the other. On the one hand, however, both were caused by a non-hemolytic anaerobic streptococcus, but on the other, the larger of the two assumed the character of an ulceration with burrowing and undermining features so pronounced as to warrant inclusion in this group of infections. Furthermore its response to specific zinc peroxide therapy was so spectacular as to add to the justification for its inclusion. This is described as Case 2 and is illustrated in Figures 5 to 9. The second of these 2 cases (Case 3) revealed no undermining or burrowing propensities but the only organism isolated was an anaerobic non-hemolytic streptococcus, no organism was present on the aerobic media. It is by no means typical of the group, clinically or etiologically, but is included in this report to illustrate the facts that an anaerobic streptococcus may invade without causing burrowing or undermining, and in the absence of these changes can be successfully attacked with non-oxygen-producing antiseptics. Sulfanilamide was used for a short period.

The third of this somewhat unorthodox group (Case 4) is one in which an anaerobic hemolytic

streptococcus was present in some profusion and also demonstrates that in milder cases oxygen production is not an essential requirement in the therapeutic agent. A small sinus communicating with the ulcer represented the only possible tendency to burrow. Despite the use of only mild local non-oxygen-producing antiseptics the sinus did not increase in extent. Undermining was not present. As in Case 3 sulfanilamide was used for a few days.

In his reports Meleney discusses the clinical picture and treatment of some 40 cases, 18 of which were given combined zinc peroxide and intensive sulfanilamide therapy (11). Since the publications of his descriptions eighteen cases have been added by others (1, 2, 4, 6, 7, 14, 15, 16, 17). Some of these (2 and 6), however, do not fit precisely into Meleney's criteria for the establishment of the diagnosis. The writer has had some detailed experience with 2 others, 1 of which (Case 2) as previously noted perhaps should not be included inasmuch as the causative agent was a non-hemolytic rather than a hemolytic streptococcus.

Conversely, in the 2 other infections here reported an anaerobic streptococcus was apparently either the sole or predominating invader, but with virtually complete absence of burrowing or undermining propensities in both. In one of these cases the infectious process due to a non-hemolytic organism progressed to complete healing with antiseptics simpler in character than that used for the undermining or burrowing type. Local antiseptics and, for a brief period, sulfanilamide were used effectively for the other caused by a hemolytic anaerobic streptococcus. Because these infections lacked the gross features Meleney describes they have not been included in this report as a particular variety of chronic ulceration.

The writer does not propose to offer an exhaustive summary of Meleney's laboratory, clinical, and therapeutic studies. These are, by this time, well known to all who are familiar with current literature. They are described in at least one popular textbook (5). It is one of the chief purposes of this paper to emphasize the desirability

Fig. 1. Case 1. Illustrating the size of the lesion on the abdomen with undermining and extension onto the thigh. A probe has been inserted under the bridge of skin to illustrate communication between thigh and abdominal ulcerations. Further extension has occurred laterally between costal margin and iliac crest with involvement of the corresponding lumbar area as illustrated in Figure 2.

Fig. 2. Case 1. A probe has been inserted into the ulcer which appeared to be an ulceration secondary to the primary abdominal lesion and strip of adhesive marks the site of the tip of the probe. The undermining extends laterally as well and communicates directly with the abdominal ulcer.

anus. Mullen and Lawrence attempted the treatment of this infection with both sulfanilamide and

of making anaerobic cultures in all chronic superficial infections. Following this, some conclusions will be offered relative to indications for the use of zinc peroxide. Parenthetically at this point mention should be made of a simple method of anaerobic culture devised by Spray and recommended by Shallow and his associates in their studies on this type of infection.

Some modifications in treatment have been suggested by various writers. Thus, while McInerney applied zinc peroxide in distilled water Pennoyer utilized hydrogen-peroxide as the suspending agent. Rhoads found that it "proved useful" to administer a zinc peroxide suspension daily as a low rectal enema in a case in which a perirectal abscess opened 4 inches proximal to the

Fig. 3. Case 1. After the first few applications of zinc peroxide the granulations have assumed a gelatinous appearance. Because of the difficulty attendant upon the removal of the preparation applied the preceding day the more thinned-out portions of the undermined skin have been removed. The white flakes are remnants of the zinc peroxide suspension applied the preceding day. The catarrhus bridges noted in Figure 1 have been removed.

Fig. 4. Case 1. This area is the same as that illustrated in Figure 3 and denotes the extent to which the seemingly small ulcer has undermined. Re-examination of Figure 3 reveals normal appearance of the skin which has been undermined by the infection. Under treatment the granulations became bright pink and flush with the level of the skin and later new epithelium began to grow in from the skin borders.

Fig 5 Case 2 This photograph illustrates the extent to which the skin has been undermined as marked off by the continuous dark line. The skin overlying the liquefied subcutaneous tissue is normal in appearance, boggy, but not particularly painful or tender. The slightly darker patch like areas are due to the brownish pus which has escaped from the incisions.

Fig 6 Case 2 A "close up" view of the external appearance of the lesion.

Fig 7 Case 2 A single application of zinc peroxide has been employed but it was found impossible to remove effectively the old preparation. The area was then opened widely, revealing the foul smelling, necrotic material illustrated. The infected area was incised, not excised, and the flaps of skin have fallen away from the underlying surface. The fascia lata is exposed on the thigh.

zinc peroxide, and efforts along the same line were made in a larger series (11). Prontosil was used unsuccessfully in 1 of a series of 6 (17) although the dosage is not stated. In 1 patient Meloney used sulfanilamide alone although the clinical

course was longer than in those treated by the combined method. Goodman with equal success cured relatively small chronic, undermining ulcerations with sulfanilamide alone, as previously noted, he did not make any anaerobic studies

Fig. 8. Case . Undermining has extended on extensively into both inguinal areas, as well as the left ischiorectal fossa and right buttock; that additional inguinal fasciolas were later placed to facilitate zinc peroxide treatment. Catheters have been inserted from the open ulcerated areas of the abdomen under the skin of both groins and out through these incisions to illustrate the communication.

Ayres reported ultimate cure with maggots in ulcerations clinically resembling these described by McLeney. Ayres spoke of the isolation of a hemolytic streptococcus but did not comment on any anaerobic studies.

The writer utilized both zinc peroxide and sulfanilamide in his 2 cases without success. However the ulcerations were unusually extensive. In both one patient was a diabetic and in each death occurred rather suddenly following intercurrent accidents. Both were making excellent progress and the infection was under complete control for some time before death occurred in the patients. Furthermore, oral specific medication was discontinued in the first patient because of suspected toxic reactions and not instituted until late in the second. Whatever control was effected over the disease in each should in all fairness be ascribed to the zinc peroxide alone. Cure was achieved in

the third and fourth cases with commoner antiseptics although sulfanilamide was used for a few days in each.

Some experiences with zinc peroxide acquired through efforts to cure the infections described in this report may prove useful to others. It is stated that not more than 25 grams of the zinc peroxide powder should be activated (heating at 140 degrees for 4 hours) at any one time. The writer, however, found it necessary to activate as much as 150 grams in one container and did not notice any appreciable reduction in the oxygen generating power of the preparation. A further and perhaps unimportant modification is associated with the necessity of maintaining constantly moist medium for the zinc peroxide suspension. McLeney accomplishes this by sealing in the medication after it has been applied, by means of gauze impregnated with vaseline or zinc oxide ointment. Possibly because of the extent of the lesion in the first case or some other undetermined factor this did not prevent appreciable drying with probable resultant reduction in oxygen generation as well as increased pain on removal of the old preparation. It was therefore decided to apply fenestrated tubes on the cream zinc peroxide suspension with one opening of tube projecting externally from between the layers of the ointment gauze. Small quantities of distilled water were then injected at 3 to 4 hour intervals during the 24. This variation proved effective in maintaining moisture.

CASE REPORTS

CASE (Figs. to 4) A 40 year old hispanic, admitted to the hospital June 21, 1938, with evidence acute peritonitis existing for about 24 hours. He has taken saline cathartics and been examined there is evidence of advancing peritonitis. Appendectomy or colectomy was immediately performed under spinal anes-

Fig. 9. Case 2. Should be compared with Figure 7 to illustrate the improvement after some 30 days of treatment with zinc peroxide. The granulations are bright, healthy pink color. Unlike Case 1, however, no growth of epithelium as noted from the skin bordering the ulcer. The opening of "barrow" at the anterior superior iliac spine may be noted. This continued to extend slowly along the crest of the ilium despite repeated negative anaerobic cultures and persistent use of zinc peroxide applied with narrow strips of gauze.

thetia and closed with stab wound drain. The appendix had ruptured and was found lying in a retrocecal position. Pertinent comments from the patient's progress notes follow.

On the fourth postoperative day, jaundice was noted and a doughy, virtually painless cellulitis of the right abdomen was present and extended on to the thigh and lower chest anteriorly on the right.

On the sixth day, sulfanilamide administration was started, cautiously due to jaundice. Eighty grains were given over a 2-day period, then discontinued for fear of further compromising the liver.

On the eighth day, the drain was removed. A foul smelling pus was released.

On the ninth day, patient pulled out the cecostomy tube. The sutures were removed. The wound edges gaped and the transversalis fascia was exposed.

On the eleventh day, he developed urinary and fecal incontinence.

On the twenty ninth day his general condition was some what improved, and the jaundice was subsiding. Icces were draining from stab wound. A slough (?) was noted within the area of cellulitis on the abdomen and thigh. Dakin's solution irrigations were instituted.

On the thirty first day improvement was noted but it was very slow in progress.

On the thirty second day azochloramide irrigation was started.

On the thirty seventh day a mixture of azochloramide peroxide was used. The icterus index was 13, blood culture, negative.

On the forty first day, anaerobic culture studies revealed the presence of an anaerobic hemolytic streptococcus. Foul pus continued to drain profusely.

On the forty fourth day a new sinus tract (burrowing area) was noted on the chest wall. The area was opened.

From the forty fifth to the seventy fifth day, there was no visible change. The ulcerating area was treated with local irrigations of urea solution, 3 per cent, and urea in hydrogen peroxide. No evidence of spread was noted.¹

On the eighty third day temperature was down to 100.5 degrees.

On the one hundredth day two new sinuses were noted which were filled with a foul smelling pus. Cultures here again revealed the anaerobic hemolytic streptococcus.

On the one hundred and twelfth day, zinc peroxide was started. The ulceration had assumed the appearance illustrated in Figure 1. It was not suspected that this communicated with an ulcer situated in the right lumbar area (Fig. 2).

On the one hundred and thirteenth day the zinc peroxide that had been applied the preceding day was rather dry, and when it was situated under wide bridges of skin as for instance on the thigh and right flank, it was difficult to remove.

On the one hundred and fourteenth day the sinuses were excised widely. The appearance following excision is illustrated in Figures 3 and 4. Zinc peroxide was reapplied daily until grafting was done on the one hundred and forty-eighth day and moisture was maintained with fenestrated tubes.

On the one hundred and twenty third day the only organism present on aerobic and anaerobic cultures was the pyocyanus.

¹During this period inquiries locally failed to elicit any information concerning the commercial availability of zinc peroxide. A letter was written to Dr. Melency asking about the medication and he advised contacting the DuPont Chemical Company, Niagara Falls, New York. In the meantime sulfanilamide (prontyllin) was again instituted and continued for a period of 7 days, then discontinued when the temperature rose to 102.4 degrees (81st day).

On the one hundred and twenty fourth day granulations were bright pink, healthy looking. The epithelium was beginning to grow into the ulcer surface from the surrounding skin.

From the one hundred and twenty fifth to the one hundred and forty seventh day local and general improvement was noted. Repeated cultures failed to reveal any organism other than the pyocyanus.

On the one hundred and forty eighth day "Seedling" grafts were peppered into the granulation on the abdomen, thigh, and back.

From the one hundred and forty ninth to the one hundred and eighty first day, successful take of most grafts was noted. By the one hundred and eighty second day there were several nummular islands of epithelium growing on the granulating surfaces. Zinc peroxide had been discontinued and normal saline dressings were used. The pyocyanus continued to grow in some profusion but repeated cultures failed to reveal any other organism. Further progress continued uneventfully until the one hundred and ninety second day when it was noted that the temperature was somewhat higher than usual (101.6 degrees). There had been a low grade elevation varying between 99 and 100 degrees throughout most of the illness. Examination failed to reveal any cause for the elevation, the granulations remained relatively clean. A careful search disclosed no new sinus tracts, the lungs were apparently clear, etc. The white cell count was 9,600 of which 73 per cent were polymorphonuclears, 22 lymphocytes, 3 monocytes, and 2 eosinophiles.

On January 6, 1939, the one hundred and ninety fifth day, the patient suddenly developed generalized clonic convulsions. Examination revealed nuchal rigidity and a positive Brudzinski sign. Non protein nitrogen was 29.5 and carbon dioxide volumes per cent was 65.6. Spinal tap revealed opaque fluid under increased pressure containing 17,000 white blood cells per cubic millimeter of which 98 per cent were polymorphonuclears. No tubercle bacilli, anaerobic or aerobic organisms were found. Mouse cultures and blood cultures were negative. Continuous spinal fluid drainage on a Bradford frame was instituted. Hourly intravenous injections of prontosil were administered.

On the one hundred and ninety sixth day patient was in a restless coma, with head pulled to the right and flaccid paralysis of the left side of the face. Breathing was stertorous. Spinal fluid was still draining. Diagnosis: Brain abscess with purulent meningitis. Temperature and pulse fell to normal levels but coma continued. At midnight, the patient expired. Consent for postmortem examination could not be obtained.

This case is typical of the infection that Melency describes, and under zinc peroxide therapy was making excellent progress. Various other antiseptics proved worthless. Death was only indirectly due to the infection. Sulfanilamide was given at different times, then discontinued because of suspected toxic reactions, undoubtedly it had nothing to do with the favorable response shown. However, in retrospect, this patient's best chance of survival might have come with earlier recognition of the character of the lesions and perhaps immediate use of peroral sulfanilamide in conjunction with zinc peroxide locally.

CASE 2 (Figs 5 to 9). A 48 year old white man, a known diabetic, was admitted to the hospital, April, 1939, with a history of having had a urethral stricture in 1931. Eleven

days prior to admission he developed evidence of perirectal abscess. It gradually increased in size then spread over the abdomen and right thigh. Shortly after admission incisions were placed over the fluctuant areas and tubes were inserted for irrigation. The pus was foul-smelling, brown, sticky material. The overlying skin was boggy not discolored, and not particularly painful or tender. Figures 5 and 6 illustrate the lesion; the dark line delineates its extent. Aerobic culture revealed mixed infection of *Bacillus coli*, *Staphylococcus albus*, *Gaffky's tetragens*, and non-hemolytic streptococcus. It is an equally profuse growth of the non-hemolytic streptococcus on anaerobic culture. Zinc peroxide treatment as instituted but due to the difficulty encountered in removing the old peroxide the infected area was incised widely; its appearance is illustrated in Figure 7. At this time burrowing was found to have extended into the left ischiofemoral fossa, downward on the most dependent part of the right buttock undermining the skin to the base of the penis. Additional incisions were placed to facilitate treatment of these areas. In Figure 8 catheters have been inserted to illustrate the communication between these incisions and the abdominal part of the infection. Following the institution of zinc peroxide therapy the character of the inflammation began to improve rapidly and by the twentieth day assumed the appearance illustrated in Figure 9. The granulations here are pink and healthy. However despite thorough treatment the infection continued to burrow along the right iliac crest although cultures from this area are repeatedly negative. A diffuse pitting edema of the thigh and leg made its appearance (about a month after admission). Sulfanilamide as then started, the thirty-second day after the institution of zinc peroxide treatment, and was continued for period of about weeks; sulfanilamide blood levels during this time ranged from 3 to 10 milligrams. Burrowing continued and the use of the oral drug was stopped. (While repeated cultures showed that the infection was under complete control, 2 to 3 times throughout the illness was there noted any growth of epithelioma. The patient's condition remained stationary until June 4, 1930, when he expired, 63 days after admission, of what appeared to be a lung embolus. Autopsy was not obtained.

Both burrowing and undermining features were present in Case 3 although progression was unusually rapid. This, of course, may have been on account of the diabetes. On the other hand the anaerobic organism was not hemolytic and therefore this case may not dovetail precisely with McIneny's criteria. However response to zinc peroxide was excellent and the patient appeared to be making good progress only to make his exitus, like the first, as the result of an unfortunate accident. The possibility of invasion by an anaerobic streptococcus was considered immediately upon admission and zinc peroxide therapy was instituted as soon as possible after the presence of such an organism had been established. As in Case 1, early continued sulfanilamide administration might have proved more effective than the use of local treatment exclusively.

Because of the non-hemolytic character of the organism one would perhaps suspect the possible eventual development of a picture of progressive

synergistic gangrene. However burrowing propensities were too pronounced; pain relatively mild and the staphylococcus present was of the albus rather than aureus variety. McIneny has written with equal lucidity on this type of synergistic infection (3, 10).

Case 3. A 53 year old white man was admitted January 4, 1929, for the treatment of tender fluctuant mass measuring 4 by 6 inches and lying directly below the umbilicus. The overlying skin was not discolored. The patient stated that he had noted occasional slight discharge oozing from the depths of the umbilicus and a day prior to admission began to notice the transference for which he was admitted. Progress notes follow.

January 7, 1929. An incision as made and the wound packed with iodoform-soaked gauze. The pus released as thick, green, foul-smelling material with an admixture of caseous particles. On culture no aerobic growth was noted, but anaerobic studies revealed non-hemolytic streptococcus.

On the sixth day after operation, improvement continued. The abscess cavity was clean and was filling in slowly. The clinical appearance was not that of burrowing or undermining type of infection.

On the eighth day after operation abscess cavity appeared to communicate with the peritoneum; the patient as having abdominal distention and good deal of pain. The white blood count was increased to 30,000. Sulfanilamide was instituted.

On the ninth day after operation pain and distention were less. Improvement continued.

On the tenth day sulfanilamide was discontinued. The blood levels of the drug for the 3-day period were 9 to 10 milligrams.

On the fifty-fourth day after operation, area was entirely healed. Patient discharged.

Case 4. A 40 year old white man was admitted to the hospital July 9, 1933, for the treatment of chronic alcoholism, alcoholic neuritis, acute arthritis of the left knee, and an acute infection of the left thigh. This infection of the thigh first made its appearance as an abscess which had been incised or 3 weeks prior to admission. Healing did not follow; however and when first seen this incised abscess presented the appearance of an irregular ulcer to 5 inches in diameter and discharging rather large quantity of thick, purulent material. A small sinus as present communicating with the ulcer. Ordinary aerobic studies revealed *Staphylococcus aureus* and hemolytic streptococcus but later anaerobic cultures disclosed "many long-claimed hemolytic streptococci." Sulfanilamide as instituted and after 3 days the amount of drainage had diminished considerably and after few more days patients of iodoform-soaked—3%—and hydrogen peroxide as used locally. Oral medication as stopped the following day when it was recorded that "discharge very slight." Local antiseptics were continued until about the forty-fifth day after the beginning of sulfanilamide treatment when the ulcer had healed completely.

Except for the small persistent sinus in Case 4, which did not progress despite the use of only simple antiseptics, burrowing and undermining were absent. In other words, it would appear that the mere isolation of an organism capable of producing the disease does not warrant the clinical diagnosis unless the typical feature of

undermining or burrowing is present. It is further apparent from Cases 3 and 4 that in the absence of such features one is justified in treating these patients with more conventional antiseptics. The use of sulfanilamide for a few days in each of the cases described may have played some part in bringing about a cure. It is possible, too, at least judging from Meleney's experience, that an earlier cure might have been produced if zinc peroxide had been used. However, this is relatively expensive and in the ambulant patient, apparently not necessary at least so long as no invasive tendencies are present. While cure might have been effected before the fifty-fourth day in Case 3 and the forty-fifth day in Case 4 by means of the combined treatment, it should be noted that Lawrence used zinc peroxide-sulfanilamide for a period of 3 months before he obtained cure in his case.

SUMMARY

Four cases are described bearing more or less definite relationships to Meleney's "chronic undermining, burrowing ulcer due to the anaerobic hemolytic streptococcus." One (Case 1) is typical in that it fits precisely in this group, the ulcer was chronic, exhibited undermining and burrowing features, was caused by the anaerobic hemolytic streptococcus, and furthermore responded dramatically to zinc peroxide treatment. In case 2 undermining and burrowing propensities were disclosed which responded equally well to zinc peroxide but was associated with a nonhemolytic anaerobic streptococcus, in other words this case may illustrate that the clinical picture can be duplicated by a different type of anaerobic streptococcus. Deaths in these patients were due to unavoidable accidents and can hardly be regarded as failures on the part of the therapeutic agent. On the contrary, the result of the use of zinc peroxide treatment in these infections was such as to lend unqualified confirmation of its effectiveness.

Cases 3 and 4 are illustrative of the fact that the significant anaerobic organism present in either Case 1 or Case 2 may be isolated in appreciable numbers from infections which do not tend to undermine or burrow. In these types cure was accomplished by simpler local antiseptics combined with short and possibly insignificant courses of sulfanilamide.

CONCLUSIONS

It would appear that hemolysis or non-hemolysis is not essential in producing the gross picture of the disease so long as the streptococcus is anaerobic. It is also apparent that the anaerobic

streptococcus may invade without causing undermining or burrowing. Treatment should depend on an evaluation of the combined factors of causative organism and character of the lesions. Based on the foregoing, the following corollaries may be presented:

- 1 The performance of anaerobic as well as aerobic culture studies is urged in all superficial infections, particularly if there is any tendency to chronicity.

- 2 If the infection is of recent origin, not extensive, and not characterized by undermining or burrowing, then treatment with the more conventional antiseptics should be instituted irrespective of the character of the organism isolated.

- 3 A burrowing, undermining, extensive or stubborn lesion associated with an anaerobic streptococcus, whether or not hemolytic, had best be attacked in accordance with the principles laid down by Meleney, namely, immediate application of zinc peroxide and oral sulfanilamide, 18 grains every 4 to 6 hours.

- 4 A careful watch should be maintained throughout the course of the ulceration for the appearance of any new undermining or burrowing areas.

VARUS DEFORMITY OF ANKLE FOLLOWING INJURY TO DISTAL EPIPHYSEAL CARTILAGE OF TIBIA IN GROWING CHILDREN

GERALD G GILL, M D , and LEROY C ABBOTT, M D , F A C S , San Francisco, California

THE development of a varus deformity of the ankle following injury to the distal epiphysis of the tibia in growing children is uncommon. Nevertheless this condition is of great interest to the surgeon because its correction is often attended by many difficulties. In this article it is our object (1) to show that the deformity follows a specific injury of the medial malleolus, (2) to emphasize that the surgeon, may, by this knowledge, prevent the occurrence and progression of the deformity by relatively simple procedures, (3) to present fundamental principles of treatment which have given excellent anatomical and functional restoration in a neglected case with severe deformity.

ANATOMY OF THE EPIPHYSEAL CARTILAGE PLATE AND THE EPIPHYSIS

In fetal life the future long bone is composed of a cartilaginous rod. The central portion of this rod, the diaphysis, is invaded by blood vessels and ossification progresses from this central region toward each end. The cartilaginous ends of this rod, known as the epiphyses, are invaded at a later date by separate blood vessels, and their centers become ossified. The periphery of the epiphysis remains cartilaginous, the distal rim becoming the articular cartilage, and the proximal portion remaining as a band of actively proliferating cartilage cells. This band or plate is known as the epiphyseal cartilage plate. Longitudinal growth occurs by a process of degeneration and calcification in the columns of cartilaginous cells which are invaded by bone forming elements from the diaphysis. Anatomically and developmentally this cartilage plate is an integral part of the epiphysis, and as such receives its blood supply from the same vessels.

RELATION OF AGE TO THE TYPE OF EPIPHYSEAL INJURY

In infancy and early childhood, the connection between the epiphyseal cartilage plate and the

diaphysis is very loose, and, on purely anatomical grounds it would be expected that shearing forces would most likely result in separation in the zone of calcifying cartilage without involvement of the cartilage plate. Haas showed that this is actually the case in young puppies and furthermore that disturbance of growth does not follow. It is of common clinical experience that, in children from birth to 9 years of age, pure epiphyseal separation as a result of indirect trauma is the rule, and deformity or disturbed growth almost never occurs. In this age group, crushing injuries alone damage the epiphyseal cartilage and give rise to disturbance of growth.

In older children, from 9 to 14 years of age, union between the epiphysis and diaphysis is more firm. This results from the fact that the band of cartilage cells becomes narrower and the line between the epiphysis and diaphysis presents an interlocking parallel surface. Consequently, in this age group, pure epiphyseal separation is rare and two main types of injury are most common.

In the first type, the line of separation may pass through the metaphyseal region up to a point where union between the epiphysis and diaphysis is very firm and the diaphysis itself becomes a relatively weaker structure than the epiphyseal cartilage. Therefore, the line of separation crosses the diaphysis, resulting in fracture. This may be properly called a fracture-separation. In this type of injury the epiphysis and the epiphyseal cartilage plate, although widely displaced are left intact. In such instances there is no direct injury to the cartilage cells and disturbed growth does not follow.

In the second type of injury, the epiphysis itself may be fractured as a result of a combination of the anatomical configuration of the region involved and the specific mechanism or direction of the force. The line of fracture may pass through the epiphysis, across the cartilage plate, and then may either proceed through the metaphysis or through the adjoining diaphysis. Only in this type of indirect injury would disturbances in growth be expected to follow. It will be shown that, due to the anatomical configuration of the

legs depending upon the age of the patient and his individual potentialities of growth

A variation in the deformity may be produced if the internal malleolus is displaced far medially (Fig 1 c). Thus Compere, 1935, reported an unusual case in a boy 14 years of age who had suffered a fracture 2 years previously at the age of 12. In this instance the bony configuration was atypical in that the medial malleolus was absent from its usual position at the ankle mortise but was fused to the shaft of the tibia at the level of a line of arrested growth about 15 centimeters above the growing cartilage plate (Fig 1 d). The articular surface of the tibia was not tilted and the cartilage plate, although not so wide as usual, was horizontal and growing. An identical case was reported by Van Assen in a girl 13 years of age who had had a fracture at the age of 10 years. In these two instances the medial malleolus must have been displaced rather far medially and slightly upward so that, when healing was complete, the malleolus had united with the shaft, but, because of insufficient contact, had failed to unite with the undamaged lateral portion of the epiphysis. After a temporary period of retardation of growth, as evidenced by the line of arrested growth, linear growth continued in almost a normal manner, leaving the malleolus fused to the shaft of the tibia to mark the level at which the injury occurred. No tilting of the articular surface of the tibia resulted because the medial malleolus did not lock the undamaged lateral portion of the epiphyseal plate to the diaphysis, as happens in most instances. A varus deformity resulted, not from a tilt of the articular surface of the tibia, as in most of these cases, but from a medial shift of the astragalus and foot due to loss of the normal medial support of the internal malleolus which was absent from its normal position.

Many other instances of disturbance of growth at the ankle have been reported following severe crushing injuries, operative procedures and infection which have given rise to various deformities but do not cause such typical and definite bony changes as results from adduction injuries.

LITERATURE

Poland, 1898, reported his case and reviewed those previously recorded by Bouchut, 1867, Rose, 1882, Hutchinson, 1885, Davies Colley, 1888, Owen, 1891, and Moulin, 1892. More recently, Smith, 1921, Baldrian, 1933, Van Assen, 1933, Brockman, 1934, Aitken, 1936, Morris and Downing, 1936, and Burrows, 1937, reported similar instances. A study of these reported cases con-

firms the fact that in most instances, the deformity follows an adduction force which results in fracture of the medial malleolus.

Correction of the deformity by osteotomy of the tibia and fibula during the growing period was found to be unsuccessful because continued growth from the undamaged lateral portion of the epiphysis of the tibia and from the fibula caused recurrence of the deformity. Ollier, however, in treating a similar deformity, successfully equalized the lengths of the tibia and fibula by chondrectomy of both epiphyses of the fibula. It is of especial interest that, as early as 1873, he performed epiphyseal fusion as a means of limiting longitudinal growth in the correction of deformity of the lower extremities. Poland, and later Brockman and Burrows, performed osteotomy of the tibia and fibula in conjunction with excision of the epiphyseal cartilage of the lower fibula, and obtained permanent correction of the deformity in growing children. McFarland, Brockman, and Burrows utilized the open wedge osteotomy of the tibia to increase the length of the leg in young children. Morris and Downing waited until growth was completed and then performed an ingenious high step osteotomy of the tibia so designed as to allow rotation and sliding of the fragments in apposition. The leg was held by a device for lengthening the tibia which allowed slow correction of deformity and lengthening.

The following case illustrates the problems presented, and the methods of their solution in the correction of this severe deformity, and the equalization of the length of the legs.

CASE REPORT

C P, a boy 15 years of age, entered the hospital on December 1, 1938. At the age of 10 years he had been struck by an automobile and his right ankle had swelled very badly. The boy's mother said that x-ray examinations made at the time of injury showed no fracture at the ankle. We were unable to obtain the films as no record of them was kept by the physician in charge of the case at that time. The foot had been encased in a plaster cast for 6 weeks and then normal activity had been resumed. Nothing abnormal was noted until 2 years after the accident when the mother observed that the right foot was offset inward and the lateral malleolus was prominent. This deformity increased to a marked degree but the boy was able to continue normal activity. He had no pain in the ankle, knee, or foot but, by reason of the inversion and shortening, he developed a limp.

His family and past history was negative. His health was good, and physical examination was negative except for the right ankle, which was seen to be in marked varus. The external malleolus was very prominent and appeared to curve around the distal portion of the tibia (Fig 2a) the internal malleolus was very small. Motions at the ankle were dorsiflexion, right 10, left 15 degrees, plantar flexion, right 45, left 45 degrees, inversion, right 30 to 45, left 45 degrees, eversion, right —40 to —30, left 0 to 10 degrees.

Fig. a, b, The mechanism of production of the typical varus deformity. c, d, The mechanism of production of the typical deformity (Compers and Van Assen's)

ankle, this type of fracture results most commonly from only one type of indirect violence

RELATION OF THE MECHANISM OF INJURY TO THE TYPES OF FRACTURE SEPARATION OF THE DISTAL EPIPHYSIS OF THE TIBIA IN GROWING CHILDREN

Blishop, 1932 made a detailed study of 32 cases of fracture-separation of the distal epiphysis of the tibia in children and found a frequency of 1 to 10 as compared to fractures of the ankle in adults. When these were classified according to the mechanism of production in the manner in which Ashhurst classified fractures of the ankle in adults, it was shown that abduction, external rotation, and torsion produced pure separation in young children but, in older children these injuries produced separation of the intact epiphysis with associated diaphyseal fracture. No fracture of the epiphysis or the epiphyseal cartilage plate resulted.

Adduction injuries, however were by far the most common, comprising 54.8 per cent of Blishop's entire series. In younger children pure epiphyseal separation occurred, but in the older group most injuries of this type resulted in a strikingly uniform vertical line of fracture running from the surface of the joint adjacent to the internal malleolus, up to the epiphyseal plate, through it, and either inward to its medial aspect or upward a short distance through the diaphysis.

Only in these cases of indirect injury is the continuity of the epiphyseal cartilage broken, and only in these is deformity to be expected. Blishop saw no instances of delayed growth or deformity

in his series but admitted that the follow-up was insufficient.

McFarland, 1932 reported that in 2 years he encountered in his English practice 23 cases of this particular epiphyseal fracture in a total series of 3,000 fractures 40 per cent of these patients developed deformity. This injury resulted most often from a fall with the feet wedged between the railings of a picket fence, and McFarland attributed the high incidence of the deformity in England, as compared to that in the United States, to the relative prevalence of picket fences in England.

THE MECHANISM OF PRODUCTION OF THE VARUS DEFORMITY FOLLOWING FRACTURE-SEPARATION OF THE MEDIAL MALLEOLUS

As McFarland pointed out, the anatomical configuration of the ankle makes injury in adduction the mechanism whereby premature cessation of growth occurs on the medial aspect of the epiphyseal cartilage plate. The astragalus is firmly held by the internal and external malleoli. Therefore lateral motion is not free, and an adducting force drives the astragalus against the rigid internal malleolus resulting in a localized fracture across it at this point. The malleolus is separated, the periosteum is torn and its attached cartilage plate suffers some loss of blood supply (Fig. 1 a). Degeneration of the cartilage follows and bony fusion occurs between the diaphysis of the tibia, the internal malleolus and the lateral portion of the epiphysis, forming a small rigid point about which the intact and undamaged lateral portion of the cartilage plate grows. The distal epiphysis of the fibula, not being involved, continues to grow and curves around the lateral aspect of the tibia forming a definite prominence in that region (Fig. 1 b). The typical varus deformity is formed in this manner. In some instances, however the fracture may be a mere crack with so little damage to the cartilage plate or its blood supply that no disturbance results. In others, the patient is of an age at which cessation of growth is so near that no deformity can be produced.

At first, because of the cessation of growth on the medial portion of the cartilage plate shortening is present only on the medial side of the ankle. Later there is usually found increasing shortness of the entire tibia as compared with that on the uninjured side. This follows because in most instances, when one portion of a cartilage plate is destroyed, the undamaged portion grows at a slower rate and fuses prematurely. Continued growth of the normal tibia gives rise to various inequalities of the comparative length of the two

legs depending upon the age of the patient and his individual potentialities of growth.

A variation in the deformity may be produced if the internal malleolus is displaced far medially (Fig 1 c). Thus Compere, 1935, reported an unusual case in a boy 14 years of age who had suffered a fracture 2 years previously at the age of 12. In this instance the bony configuration was atypical in that the medial malleolus was absent from its usual position at the ankle mortise but was fused to the shaft of the tibia at the level of a line of arrested growth about 15 centimeters above the growing cartilage plate (Fig 1 d). The articular surface of the tibia was not tilted and the cartilage plate, although not so wide as usual, was horizontal and growing. An identical case was reported by Van Assen in a girl 13 years of age who had had a fracture at the age of 10 years. In these two instances the medial malleolus must have been displaced rather far medially and slightly upward so that, when healing was complete, the malleolus had united with the shaft, but, because of insufficient contact, had failed to unite with the undamaged lateral portion of the epiphysis. After a temporary period of retardation of growth, as evidenced by the line of arrested growth, linear growth continued in almost a normal manner, leaving the malleolus fused to the shaft of the tibia to mark the level at which the injury occurred. No tilting of the articular surface of the tibia resulted because the medial malleolus did not lock the undamaged lateral portion of the epiphyseal plate to the diaphysis, as happens in most instances. A varus deformity resulted, not from a tilt of the articular surface of the tibia, as in most of these cases, but from a medial shift of the astragalus and foot due to loss of the normal medial support of the internal malleolus which was absent from its normal position.

Many other instances of disturbance of growth at the ankle have been reported following severe crushing injuries, operative procedures and infection which have given rise to various deformities but do not cause such typical and definite bony changes as results from adduction injuries.

LITERATURE

Poland, 1898, reported his case and reviewed those previously recorded by Bouchut, 1867, Rose, 1882, Hutchinson, 1885, Davies Colley, 1888, Owen, 1891, and Moulin, 1892. More recently, Smith, 1921, Baldrian, 1933, Van Assen, 1933, Brockman, 1934, Aitken, 1936, Morris and Downing, 1936, and Burrows, 1937, reported similar instances. A study of these reported cases con-

firms the fact that in most instances, the deformity follows an adduction force which results in fracture of the medial malleolus.

Correction of the deformity by osteotomy of the tibia and fibula during the growing period was found to be unsuccessful because continued growth from the undamaged lateral portion of the epiphysis of the tibia and from the fibula caused recurrence of the deformity. Ollier, however, in treating a similar deformity, successfully equalized the lengths of the tibia and fibula by chondrectomy of both epiphyses of the fibula. It is of especial interest that, as early as 1873, he performed epiphyseal fusion as a means of limiting longitudinal growth in the correction of deformity of the lower extremities. Poland, and later Brockman and Burrows, performed osteotomy of the tibia and fibula in conjunction with excision of the epiphyseal cartilage of the lower fibula, and obtained permanent correction of the deformity in growing children. McFarland, Brockman, and Burrows utilized the open wedge osteotomy of the tibia to increase the length of the leg in young children. Morris and Downing waited until growth was completed and then performed an ingenious high step-osteotomy of the tibia so designed as to allow rotation and sliding of the fragments in apposition. The leg was held by a device for lengthening the tibia which allowed slow correction of deformity and lengthening.

The following case illustrates the problems presented, and the methods of their solution in the correction of this severe deformity, and the equalization of the length of the legs.

CASE REPORT

C P, a boy 15 years of age, entered the hospital on December 1, 1938. At the age of 10 years he had been struck by an automobile and his right ankle had swelled very badly. The boy's mother said that x ray examinations made at the time of injury showed no fracture at the ankle. We were unable to obtain the films as no record of them was kept by the physician in charge of the case at that time. The foot had been encased in a plaster cast for 6 weeks and then normal activity had been resumed. Nothing abnormal was noted until 2 years after the accident when the mother observed that the right foot was *offset* inward and the lateral malleolus was prominent. This deformity increased to a marked degree but the boy was able to continue normal activity. He had no pain in the ankle, knee, or foot but, by reason of the inversion and shortening, he developed a limp.

His family and past history was negative. His health was good, and physical examination was negative except for the right ankle, which was seen to be in marked varus. The external malleolus was very prominent and appeared to curve around the distal portion of the tibia (Fig 2a) the internal malleolus was very small. Motions at the ankle were: dorsiflexion, right 10, left 15 degrees; plantar flexion, right 45, left 45 degrees; inversion, right 30 to 45, left 45 degrees; eversion, right -40 to -30, left 0 to 10 degrees.

Teleroentgenograms showed that the articular surface of the tibia as tilted medially 30 degrees (Fig. 3). By measurement, the lengths of the right and left tibia were 14 1/2 inches, tip to tip—straight line—right, 14 1/2 left, 14 1/2 inches; tibia, medial edge of superior articular surface to tip of medial malleolus, right, 14 1/2 left, 14 1/2 inches; lateral edge of superior articular surface to lateral tip of inferior articular surface, right, 14 1/2 left, 14 1/2 inches.

Realizing the difficulties encountered by previous surgeons, it was decided to plan the operation in detail by means of x ray films and dissections on the cadaver. The site and type of osteotomy were decided upon by tracing the teleroentgenograms of the deformed side and the normal side and by trial and error it was found that a very low oblique osteotomy of the tibia, passing laterally and distally would, if opened on the medial side, give added length, full correction, and a normal contour to the ankle (Fig. 4).

In order to safeguard the procedure a modification of a tibial lengthening apparatus was devised. It consisted of two parallel longitudinal threaded bars held at each end by curved metal pieces which were adjustable as to width. Pin carriers were mounted on the bars. These were constructed so as to hold each pin securely and allow it to be raised or lowered separately. Threaded stainless steel pins were to be used as they would allow no lateral sliding of the bones on the pin. Traction was to be obtained by the use of steel springs which would slide on the parallel bars and would be tightened by nuts threaded on the bars.

When the apparatus was tested on the cadaver it was found that, when the lower fragment of the tibia was rotated downward and around, the heel cord, the extensors and flexors of the toes, and the tibialis anticus and posticus tendons became tight and prevented rotation of the distal fragment of the tibia. It was therefore decided that these tendons should be lengthened. It was also noticed that the lower fragment of the fibula must move independently of the upper fragments of the tibia and fibula. As the interosseous membrane would tend to limit this motion, it was decided to separate this membrane from the bones about 1 inch above and below the sites of osteotomy of the tibia and fibula.

The operation was performed on December 8, 1938. Three incisions were used, the anteromedial portion of the ankle being spared because of the possibility of slough.

The first, or anterolateral, incision, was begun about 3 1/2 inches above the ankle joint and as carried vertically downward for about 10 inches, being placed approximately over the course of the tendon of the extensor hallucis muscle. The tendons of the tibialis anticus, extensor hallucis, and extensor digitorum communis were exposed, and each as lengthened by simple Z method and sutured with silk. This wound as then closed.

The second incision, as made on the posteromedial aspect of the ankle, beginning at the level of the medial malleolus, and as carried vertically upward for distance of 5 inches. The tendons of the tibialis posticus and flexor digitorum communis were immediately isolated. The posterior tibial vessels and nerves, are isolated, dissected free, and carefully retracted. The Achilles tendon was exposed and lengthened about 1 1/2 inch by the method of Hoke. The posteromedial aspect of the tibia was exposed by retracting the neurovascular bundle laterally and the flexor digitorum communis tendon medially.

The third, or posterolateral, incision was begun just posterior to the tip of the fibula and as carried upward for distance of 3 1/2 inches. The distal fibula as exposed and, with sharp chisel, very thin slice of bone was removed from the surface of the fibula to expose the epiphyseal cartilage which as then excised.

The interosseous membrane as exposed and cut for distance of 1 1/2 inches to free the distal portion of the fibula from the tibia. The separation as continued downward thus partially dividing the syndesmosis at the tibiofibular joint. In this region many branches of the peroneal artery were cut and tied. With the peritoneal elevator the lowermost fibers of origin of the flexor hallucis longus, are separated from the medial surface of the fibula. With the Mayo saw, an oblique osteotomy of the fibula, passing distally and laterally, as performed about 1/2 inch above the epiphyseal line. A Bennett retractor as placed through the interosseous membrane around the anterolateral aspect of the tibia to protect the anterior tibial vessels and nerves. With the posterior surface of the tibia thus exposed, drill hole was placed through the posterior cortex of the tibia about 1 inch proximal to the site of the osteotomy of the fibula. With the Mayo saw the lateral half of the tibia was cut at an angle of 45 degrees with the shaft of the tibia.

In similar manner, but through the posteromedial incision, the medial half of the tibia as divided in the same line.

A Matthew's wire was placed through the tibia in the region of the tibial tubercle, 1 right angles to the shaft and second one placed only through the medial side of the tibia about 10 inches below and parallel to the first. These pins and the Matthew's stirrup are incorporated in the lengthening apparatus and correction as begun. Moderate correction as immediately obtained, the osteotomy opening about 1/2 inch on the medial side. The tendon of the tibialis posticus muscle became tight and was lengthened by simple Z method. Flakes of cancellous bone are obtained from the posterior flares of the femur and are packed into the open wedge in the tibia. The wounds were closed and the patient was placed in bed with the leg suspended in Thomas splint. Its fixation attachment and the attached apparatus as suspended separately with weights (Figs. 5 and 6). Unfortunately the apparatus as not counterbalanced sufficiently and in 5 days an area of pressure necrosis appeared on the heel. This was later covered by Blake graft with excellent results.

Circulation as excellent at all times and 8 days after operation lengthening as begun again. On December 20, some flexion of the terminal phalanx of the great toe was noted. This, no doubt, was caused by the lengthening of the extensor hallucis without lengthening of the flexor hallucis. This was not distressing, however and was easily corrected by traction with small elastic bands.

Lengthening as continued slowly. Heel pain until January 4, 1939, when full correction had been obtained. At this time tendency toward calcaneus was noted. On February 1, almost 2 months after operation, traction was released. Two days later unopposed cast was applied while the foot was still in the apparatus and the pins were

Fig 2 a, left, Photograph showing marked varus deformity 5 years after original injury b, Photograph taken on January 23, 1940, 13½ months after operation, showing the end result

Fig 3 a, Right tibia b, Left tibia The lower articular surface of the right tibia is tilted 30 degrees Note the overgrowth and curvature of the external malleolus

removed when the cast had hardened Clinically the osteotomy seemed to be solid A walking iron was applied and the patient walked in this until March 30, when it was removed and he walked without support There was no pain in the ankle but he still had a slight lump due to the shortening which remained Some edema occurred, but this gradually disappeared

On April 6, 1939, teleroentgenograms of the tibia showed the following measurements fibula, tip to tip—straight line—right 15¼, left 15⅜ inches, tibia, medial articular ledge to internal malleolus, right 15, left 16 inches

The medial side of the right tibia had been lengthened ¾ inch and the left tibia had grown slightly during the time of observation (Fig 7)

Because it was thought that the difference of 1 inch in length would probably increase to about 1¼ to 1½ inches at completion of growth, it was decided to close the upper epiphyses of the tibia and fibula of the normal left leg We estimated that, by performing such a procedure, the difference of 1 inch might be decreased to ¾ or ½ inch through growth in the proximal epiphysis of the right tibia Accordingly this operation was performed on June 17, 1939, and at the same time the right foot was gently manipulated to increase the motion at the ankle

This patient was discharged from the hospital on July 2, 1939, walking very well with excellent power in all muscles Motions of the right ankle were as follows dorsiflexion, 10 degrees, plantar flexion, 30 degrees, eversion, 10 degrees, inversion, 10 degrees

He was last seen on February 2, 1940, 14 months after operation At that time the correction had been maintained and he had full use of his foot and ankle, even indulging in such strenuous sports as basketball and football without pain (Fig 2b) Teleroentgenograms showed that the inequality in length had not changed although the upper epiphysis of the right tibia was still unfused (Fig 8) It is probable that the expected decrease in the inequality will not be obtained as the skeletal maturation of this boy is rather far advanced

TREATMENT IN EARLY AND ADVANCED CASES

The surgeon treating fresh fractures through the medial portion of the distal epiphysis of the tibia should insist upon careful radiological check-up every 6 months until it is certain that no disturbance of growth is developing The earliest sign of impending difficulty is an area of fusion between the medial malleolus and the diaphysis

Fig 4. Proposed plan of operative correction Compare with Figure 7 to see how closely this was achieved

Fig. 5 Limb incorporated in lengthening apparatus and suspended in Thomas splint after operation

with the disappearance of the clear area occupied by the epiphyseal cartilage plate. If it becomes obvious that varus deformity is developing and the child is of an age which the amount of growth to be expected would cause considerable deformity, simple fusion of the lateral growing portion of the distal epiphysis of the tibia and the distal epiphysis of the fibula of the affected leg would result in clinical cure as the other joints of the foot could easily compensate for the minor tilt already present. Attendant fusion of the distal epiphyses of the tibia and fibula of the normal leg would then assure practical equality in the length of the legs at full growth. In this manner relatively simple procedures would save the patient not only from the discomfort of the developing deformity but from a major operative procedure in the future.

The objection might then be raised that this procedure would give rise to too great a decrease in total height. From the age of 9 or 10 years, however, the growth from the distal epiphysis of the tibia amounts to no more than 2 inches in most cases, so that this loss would be of no great consequence if the legs maintained equal length. In older children the loss in height would be even less.

For the patients who have considerable deformity when first seen, but who are still growing, Poland, Balkman, Van Assen and McFarland advocated delay in the correction of deformity until near the time for cessation of growth, unless disturbances in the knee or foot cause pain or discomfort. In the light of our present knowledge this course does not seem justifiable.

During the production of this deformity small compensatory changes develop in the joints above and below it, so that when the main deformity

itself is fully established compensatory changes in the small joints of the foot are already present. This was clearly shown in our case when it was found that had the articular surface of the tibia been brought to an angle of 90 degrees with the line of the shaft, the foot would have been carried into a position of very evident valgus.

For this reason it seems much more reasonable to correct the deformity immediately and Elie Brockman, to close the distal epiphysis of the fibula and the growing lateral portion of the epiphysis of the tibia. In order to insure that the two legs will be of nearly equal length at full growth, the correction should be accompanied by closure of the distal epiphyses of the tibia and fibula of the normal leg. To equalize discrepancy in length of the tibias already present, closure of the upper epiphyses of the tibia and fibula of the sound leg could be performed at the proper time as determined by known rates of growth.

In the cases in which deformity is already advanced, correction should be planned to give as much increase in length and anatomically perfect a result as possible. Added length is obtained by an osteotomy wedged open on the medial side. A low oblique osteotomy planned so that it passes through the region of the deformity will give added length and a good anatomical and cosmetic result, and will not merely insert another deformity in the opposite direction as does the usual higher osteotomy. In the growing child the low oblique osteotomy will also accomplish closure of the growing lateral portion of the cartilage plate as it passes into the cartilage on the lateral side. This osteotomy passes through a region of the tibia too where union is sure and rapid.

Cancellous bone from the ilium, in the form of thin slices or flakes, is suggested as an advance

Fig 6 Roentgenograms taken 13 days after operation. The tilt of the articular surface of the tibia is almost fully corrected. Notice the iliac bone packed into the osteotomy site in the tibia.

Fig 7 Roentgenograms taken 4 months after operation. Complete union present.

geous and easily obtainable material to fill in the wedge. Because of its plasticity, it packs into position easily and adjusts to the increasing size of the wedge during the slow postoperative correction of the deformity. One of us (LCA) has used cancellous bone from the ilium in a great diversity of conditions for many years. Its relatively early revascularization and reossification when compared to that of cortical bone has always been impressive. When used in filling bony defects where strength and rigidity are necessary, wedges of the desired shape may be cut from the full thickness of the ilium. Thus a thin, rigid shell of cortex surrounds the cancellous bone giving it the necessary strength but retaining the advantage of rapid revascularization.

Having planned a procedure designed to give a good anatomical and functional result, it is necessary that the surgeon insure its attainment. Many times it is seen that such planning goes to naught at surgery because of the impossibility of being absolutely certain that complete and full correction is obtained. Furthermore, often after the position obtained is apparently satisfactory, by the time the wound is closed, and the cast applied, the position of the fragments is markedly altered. For these reasons some modification of a tibial lengthening device should be used in the cases

Fig 8 Teleroentgenograms taken on January 23, 1940, 13 1/4 months after operation. Shortening of three-quarters of an inch still present.

in which marked deformity and shortening are present. It should be so designed that it can be applied under sterile conditions at surgery holding the correction under full view, and allow adjustment after operation with careful radiological control. This was done with great success by Morris and Downing and in the case reported in this paper.

Lengthening of the tendinous structures is suggested in the more advanced cases. The interosseous ligament should be divided as it will tend to restrict movement of the fragments toward correction. In these cases the anterior and posterior tibial tendons are very short and should be lengthened to give easy correction of the deformity.

CONCLUSIONS

1. Adduction injuries in growing children, resulting in fracture-separation of the medial malleolus may lead to premature cessation of growth in the medial portion of the distal epiphyseal plate of the tibia. Continued growth from the uninjured lateral portion produces a varus deformity and a shortening of the tibia.

2. The surgeon treating this type of fracture should insist upon careful follow-up and repeated x ray examinations until it is certain that no disturbances of growth may result.

3. If deformity is seen to be developing fusion of the distal epiphysis of the fibula and the lateral growing portion of the epiphyseal cartilage plate of the tibia of the affected leg should be performed immediately. This should be accompanied by closure of the distal epiphyses of the tibia and fibula in the normal leg in order to maintain equality in final length of the tibiae.

4. In the well developed deformity in growing children, correction must include closure of the lower epiphysis of the fibula and the lateral portion of the distal epiphyseal cartilage of the tibia of the affected leg to prevent recurrence of the deformity. This should be accompanied by fusion of the distal epiphyses of the tibia and fibula of the normal leg to prevent further inequality in the length of the tibiae.

5. Correction of the deformity can best be accomplished by a low oblique osteotomy passing through the area of the curvature. The wedge should be opened on the medial side. Ilac bone is suggested as a convenient and advantageous material with which to fill in the wedge.

6. In the severe cases division of the interosseous membrane between the osteotomy sites,

and lengthening of the anterior and posterior tibial tendons is advised.

7. In the cases with severe deformity a lengthening device is suggested as a method of insuring full correction as planned.

8. Equalization of inequalities in the length of the tibiae already present may be accomplished by closures of the appropriate epiphyses.

FRACTURES OF BOTH BONES OF THE FOREARM IN CHILDREN

BOARDMAN M BOSWORTH, M D, F A C S, New York, New York

SHAFT fracture of both bones of the forearm is not an uncommon injury among children, particularly in the younger age group. From the standpoint of both function and cosmesis the treatment of such fractures is important. Only by a careful examination of the end-results in a series of these cases can the relative merits of different forms of treatment be judged.

With this purpose in mind all shaft fractures of both bones of the forearm in children 16 years of age and under, treated in the outpatient department and wards of St. Luke's Hospital during the 7 year period from 1932 to 1938 inclusive, have been critically analyzed.

There were 50 patients in this series. Males outnumbered females two to one. The average age was 9 years, but 31 of the children (nearly two-thirds) were aged 10 or under. Undoubtedly this young age accounts for the fact that in 15 patients, 28 percent of the group, the fracture of both bones was of the greenstick variety. The 35 other fractures were complete, of radius and ulna.

The right forearm was broken 24 times, the left 26. Direct trauma was the known cause of injury in only 1 case, trauma was indirect in 36 and not recorded in 13. In most instances the child "fell while playing." Only 3 fractures were compound. Overriding was present in 11 cases.

Colles' fractures and epiphyseal separations have not been included in this series. In all but 2 cases both radius and ulna were broken at approximately the same level. Four were fractured in the proximal third, 18 in the middle third, and 26 in the distal third.

The use of some form of general anesthesia was recorded in 21 patients. In 3 cases reduction was not required, in 2 cases reduction was performed without anesthesia, and in 24 cases anesthesia is not mentioned. Local anesthesia, so far as can be determined, was not used.

For immobilization, anteroposterior plaster splints were usually applied to include the wrist and palm but not the elbow. In 5 of the 11 cases in which there was overriding the splint was made to include the elbow, in the 6 others it is not recorded whether the elbow was immobilized. Some form of immobilization was maintained an

average of 4 weeks and the patient was discharged after an average period of 5 weeks following reduction, excepting 4 patients who were watched between 3 and 4 months. In only 1 case was it recorded that fluoroscopy was used during reduction, though the fluoroscope may have been used in the others.

Physiotherapy consisting of baking and light massage was used in about half the cases, though when it was commenced and how long continued could not usually be determined from the record.

Six children refractured both bones through the original fracture site: 1 at 5 weeks, 4 at 3 to 4 months, and 1 at 1 year.

FOLLOW-UP

Of the whole group it was possible to trace 32, or 64 percent. Lapse of time and a shifting population account for the loss of the others from follow-up. In all but 6 of the cases followed the child was found only after an exhaustive personal search through a maze of public and parochial schools and tenements in 4 boroughs of the city.

This follow-up includes physical and x-ray examination as well as bilateral measurements of the forearm length and wrist circumference of each child and an inspection of the carrying angle. The average follow-up period was 5 years. No case has been included which was seen less than 1 year and 5 months after initiation of therapy. Several represent an end-result of more than 7 years.

Whipple and St. John, in reporting the results of fracture of both bones of the forearm in 86 children 15 years of age and under, who were followed for an average of 18 months, concluded that open reduction of such fractures is unnecessary. Bagley more recently, in reviewing 176 similar cases, came to the same conclusion.

The results in this series of cases from St. Luke's Hospital accord with their findings. There were no clinically bad results among the patients personally followed. In no case did shortening of the forearm occur, and in only one case was there a demonstrable decrease in the carrying angle, this was in a child who had subsequently been treated in another hospital for refracture of the same forearm. In but 2 cases was there a differ-

Fig. 2. W.S.I. aged 3 years. Radius displaced and overriding. Double fracture of ulna. b, Closed reduction within hour of injury. Still has 66 per cent displacement of radius and clear angulation of ulna. Result at 3 years.

ence in the circumference of the two wrists in both the fracture was within 2 inches of the distal epiphyseal line with an increased wrist circumference of 1/2 inch in one case and 3/4 inch in the other on the affected side. All three compound cases healed *per primam*. No complications resulting from the administration of anesthesia were recorded.

CLOSED REDUCTION

Unless one is familiar with the excellent ultimate results ordinarily obtained by conservative

Fig. 3. V.C. aged 5 years. Closed reduction soon after injury. There is still 75 per cent dorsal displacement of the distal fragments of both bones. b, Result at 4 years and 4 months. No evidence of displacement remains.

Angulation of the ulna has disappeared. Displacement of the two sections of the radius has ceased. Moderate volar bowing of ulna is barely perceptible upon clinical examination.

treatment of this fracture in youngsters, his natural dismay at failure to secure 100 per cent anatomical reposition of fragments on attempted closed reduction is very apt to force him into an unnecessary operative procedure. As a matter of fact it is surprising how often a good reduction can be obtained by simple manipulation even in the presence of marked displacement of both bones. Furthermore in contrast to adults, children exhibit a phenomenal capacity to re-establish the normal length, alignment and continuity of fractured bones even when there is gross displacement (Figs. 1 and 2) and overriding (Fig. 3) after reduction and immobilization have been carried out.

Twenty five patients treated by closed reduction were followed. Both anatomical and functional results were excellent in 1. Of the 4 children remaining 2 had good anatomical results with excellent function in one and fair in the other, 1 had a fair anatomical result with good function, and 1 patient had only a fair result both anatomically and functionally. This last is the child who sustained the decreased carrying angle mentioned. She had had a refracture of both bones treated in another hospital 1 year after the primary fracture and over 4 years preceding this follow-up.

The x-ray results in this group of closed reductions were excellent in 12, good in 3, and fair in 3. Solid bony union was demonstrated in every case. In no case did cross union occur between radius and ulna.

Fig 3 a, R S, aged 13 years Third attempt at closed reduction within 24 hours of injury Complete displacement and overriding of distal ulnar fragment persists
b, Result at 7 years and 4 months No perceptible defect

OPEN REDUCTION

So satisfactory are the results of conservative treatment of these fractures in children that operative interference need rarely be employed. Actually, 4 patients in this series were subjected to open reduction, an operative rate which is admittedly too high. In 2 cases simple replacement of fragments under direct vision was performed. In a third case the ulnar fragments were fastened with a loop of wire passed through drill holes in the bone and in the fourth case similar fastening was accomplished with chromic catgut.

All 4 patients were followed. One had an excellent anatomical and functional result, 2 had a good anatomical result with excellent function, and one obtained a good result anatomically and functionally although he had non-union and pseudarthrosis of the ulnar mid-shaft, which could not be detected clinically.

The x-ray results of open reduction were good in 2 cases, fair in another and bad in the fourth. Cross union between radius and ulna did not occur and bony union was obtained in 3 cases. The fourth, classed as a bad x-ray result, shows non-union of the ulnar mid-shaft with a pseudarthrosis, though the radius is solidly united. As a result of this review it is now felt that all 4 open reductions could probably have been avoided, with ultimate results in every way at least as satisfactory as those obtained.

SUMMARY

1 During the 7 year period from 1932 to 1938 inclusive, 50 children aged 16 years and under were treated in the outpatient department and wards of St. Luke's Hospital for shaft fractures of both bones of the forearm.

2 Of these, 32 were personally examined and roentgenographed at an average of 5 years following injury.

3 Twenty-five of the 32 were treated by closed reduction with excellent anatomical and functional results in 21 and no bad result.

4 Four were subjected to open reduction with satisfactory results in 3 cases and a good clinical result in the fourth despite a non-union and pseudarthrosis of the ulna.

CONCLUSIONS

In children with shaft fractures of both bones of the forearm, complete anatomical reduction with end-to-end apposition of the fragments is not essential to excellent functional and cosmetic recovery. Open reduction of such fractures in children is rarely indicated.

VITTORIO PUTTI

THE Editors of SURGERY GYNECOLOGY AND OBSTETRICS announce with regret the death on November 1 1940, in Bologna Italy of Professor Vittorio Putti, one of the great orthopedic surgeons of the world.

Professor Putti was born March 1 1880. In 1914 he succeeded Professor Codivilla as director of the Istituto Ortopedica Rizzoli and during the first world war was chief surgeon at the Institute. He founded the periodical, *La Chirurgia degli organi di movimento* and was one of the founders of the International Society of Orthopedic Surgery and Traumatology.

Professor Putti gave several lectures in the United States—the last in 1933 at the meeting of the American College of Surgeons in Chicago when he discussed the subject of bone lengthening. He was honored in many countries for his outstanding abilities as a surgeon and teacher.

A DECADE OF CONSERVATIVE TREATMENT OF INTESTINAL OBSTRUCTION

IN the past decade there have been two notable contributions to the treatment of intestinal obstruction (a) decompression of the distended bowel and (b) an appreciation of the physicochemical changes incident to high intestinal obstruction. Collier states that decompression is the greatest single technical contribution to abdominal surgery of the past ten years. Without doubt, the credit for putting this form of treatment on a rational basis belongs to Wangensteen.

Until a few years ago it was generally admitted that there had been very little progress in reducing the mortality of acute intestinal obstruction. Besides the peritoneal administration of fluid and electrolytes, the treatment consisted chiefly of enterostomy with or without release or removal of the obstructing mechanism. The average mortality from these surgical procedures was from 40 to 100 per cent depending upon the duration and nature of the obstructing lesion, the condition of the patient, and the surgical procedure performed.

Conservative therapy in cases of ileus consists of saphonage drainage to an indwelling intestinal catheter (Wangensteen or Miller Abbott tubes), proper fluid and electrolytic balance, judicious sedation, and above all an appreciation of the limitations and indications for this method of treatment. Fine has suggested the inhalation of 95 per cent oxygen to relieve the gaseous distention in intestinal obstruction. This is a valuable adjunct but the best results are obtained when combined with saphonage drainage of the bowel.

There is much to be learned, however about intestinal obstruction. The diagnosis of the type of ileus is of paramount importance and depends upon a close correlation of the history, physical examination, and roentgen-ray findings. At times it is difficult to differentiate between a strangulating obstruction and a simple mechanical ileus, but all agree that such patients should be operated upon. The mortality of operations for strangulating obstruction is far from ideal; better surgeons have a lower mortality for gastric resection than for strangulating obstructions of the gut. It will be interesting to see what progress will be made in the next decade in the treatment of ileus.

CHARLES E. REA.

WAR SURGERY

GREAT emergencies arouse men and nations to great effort. If there is any compensation for the tragic destruction of lives, of property and of ideals that results from war it must be found in the greater tolerance and kindness that come from sharing common privation and danger and the inventions that are born of dire necessity.

Every war from the beginning of time has stimulated interest in surgery but, too often, when the war has ended, the hard won lessons have been forgotten. Now again, papers on war surgery are finding their way in increasing numbers into surgical literature and soon, doubtless, demands for "short courses" in war surgery will be made on medical schools, clinics and medical groups.

Under the guidance of an illustrated press and of vivid portrayals of scientific progress skillfully dramatized by laymen for laymen it is easy to visualize "war surgery" as something new and fascinatingly different from the prosaic surgery of civil life. As a matter of fact it differs only in one respect—that large

numbers of seriously injured individuals suddenly confront the surgeon, demanding skillful and efficient care.

To cover open wounds with sterile dressings, to immobilize injured extremities, to relieve pain with sedatives and administer antitetanic serum, and then to transport wounded men rapidly and safely to surroundings where they can receive surgical care are essentially problems of organization. To work out such organization demands the best thought available to execute the plan requires only intelligence, co-operation and elementary training, not prolonged medical training.

When the wounded patients reach a surgical center again it requires the keenest diagnostic ability to determine which patients demand immediate attention, which can wait for a few hours, which can be evacuated with minimum risk. The important consideration is that actual surgical treatment, once begun, should be the same treatment accorded the man injured in a factory, in a home, or on Michigan Boulevard.

In recent years we have often heard the terms "industrial surgery," "traumatic surgery," "office surgery," etc. and have not heard often enough the term "good surgery." There is only one type of surgery that deserves emphasis—the good surgery that the injured patient requires, no matter where or how he may have been injured. There must be one best method of treating a compound injury and that method cannot be learned in short "refresher courses" but only from teaching and demonstration in medical school, from first hand observation and practice in hospital internship and residency and finally from persistent and conscientious application of sound surgical principles in daily practice.

War does drive home some simple lessons and basic principles that are too often neglected in medical school and hospital because

of the lure of more appealing tasks. There is no new magic in petrolatum and plaster, but there is magic in undisturbed rest and freedom from exposure to the constant re-infection too often introduced into open wounds by careless fingers and droplets from uncovered mouths and noses. There is no new magic in hasty excision of devitalized wound edges and immediate closure of an open wound, perhaps after filling it with sulfanilamide crystals. There

may be some magic in laying sulfanilamide crystals under the occluding dressing of an open wound that cannot be surgically treated immediately after injury, so as to produce temporary bacteriostasis, but the real magic lies in transforming contaminated wounds into clean surgical wounds in the simplest possible way and without mechanical or chemical trauma of the living tissue upon which healing depends.

SUMNER L. KOCH

are given concerning white, green, yellow, black, red, and leaden colored urines. Special chapters pertain to cloudy urines or those with sediments and granular deposits and odor of urines. In many of these prognostications the patient is adjudged suffering from anorexia, dyspepsia, clogged liver (?), weakness of the extremities, all common to many different ailments.

At any rate, urine divination or uroscopy was attacked in no uncertain terms directly or by telling sarcasm which latter method is often more effective than the best developed logical and scientific argument.

The most amusing story exemplifying the latter type of attack is told of the illustrious and arrogant Dr Radcliffe (1650-1714), who was known not only for his medical skill but also for his plainness and coarseness and who was nevertheless an early possessor of the famous *Gold Headed Cane*¹, a book which every medical man should read.

It is stated that on one occasion a woman called on this famous doctor with a urine glass or receptacle similar to the one here represented (Fig 1), and dropping a curtsy asked him to determine the nature of her husband's illness and

to prescribe for his relief, the patient being 4 miles off. Dr Radcliffe asked for the vessel and after looking at it inquired of the patient's trade. On learning that he was a bootmaker the doctor retired for a moment with the urine glass and after emptying its contents and replacing it with a more recent sample of urine, returned it to the anxious cobbler's wife with a statement to the effect that if her husband would undertake to make for him, Dr Radcliffe, a proper pair of fitting boots he would prescribe for him and his "distemper" by a similar examination.

It was Dr Willis who excoriated the uroscopists of his time in these words in chapter VI, of his work already referred to, as well as the initial paragraph of chapter VII where he writes as follows —

"These were what I had to say concerning the Judgments of Urine not collected from the vain Traditions of Quacks but what are consonant to reason and truth. Besides I know there are ordinarily delivered by Medicasters and Old-Women almost an innumerable company of Rules and Directions of Urine-Divination that the urinal is no sooner suspected but they will undertake to divine, whether the Patient be subject to the Passions of Love or Sadness, whether a Woman hath conceived with child or not, or whether it shall be a Boy or a Girl and an hundred other the like, in which using a vain conjecture, they either

¹The Gold Headed Cane. By William MacMichael. First published in 1828 and republished many times and most recently by Paul Hoeber Inc., New York, 1926.

impose by their confidence on the minds of the credulous, or (which is more frequently their custom) by a cunning craftiness they other ways sift out the matter by inquiring and falsely ascribe it to their knowledge in the inspection of Urine." And "although the business of the Examination and Inspection of Urines seems commonly only a simple thing (*viz.* the Medicastrs and Quacks for the most part behold the Urine sent in a Glass, shake it a little and presently give Judgment) yet to those who honestly endeavor the recovery of the sick the matter seems a little more intricate and they use to observe several circumstances covering Judgment by Urine which being omitted, nothing indeed can be certainly or directly learnt in the Medicinal Practice for the Urinal."

Fohn¹ who centuries later became the Father of modern urinalysis was anticipated by Willis who recognized that a knowledge of the volume color consistency and content of sound urines was necessary before attempting to investigate the quantity and color of "sick peoples urines," which

Willis describes. His analysis, however is but a variant of the so-called "apagryic analysis of Paracelsus. It is curious that in this exposition no mention is made of his own discovery of the sweet character of the urine of some diabetics made seven years previously ("Cur autem *hæmatur sacchari, aut mellis ex mire dulcorat, notis vindice dignus est*")²

As for the rest, Willis was aware of the fact that he had contributed very little for he ends his treatise on urines, thus

And thus, Sir at length you have the Doctrine or Method of Separation of Urine, such as our unskillfulness hath rendered it. I desire you would be pleased not only to pardon the errors and bareness of this Discourse, but also to excuse it in other things, because at first writ by your persuasion, and then by your command and request made publick. Wherefore pray take care of this child hardly brought forth and almost so abortive, and as it were exposed and deservedly laid at your door without portion. Farewel.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE work entitled *The Therapeutics of Internal Diseases*¹ edited by Blumer is to be published in four volumes, the first two of which are reviewed herein. Appreciating the difficulty in editing a work on an ever changing subject such as therapeutics, Dr Blumer states, "Any work on therapeutics can only attempt to cover the subject as it exists at present." Nevertheless, an excellent, broad groundwork has been laid and probably will require little change in the future. Volume 1 covers the principles of therapeutics, discussing extensively the various phases of physiotherapy, nutrition and dietetics, endocrine, serum and vaccine therapy, and the principles underlying nonspecific therapy and bacteriophage. In the chapter discussing the principles underlying treatment in psychiatry, there is some duplication of subject matter taken up in previous chapters. Section 2 includes special therapeutic technique, beginning with oral medication and prescription writing and ending with rectal, parenteral, intradermal, hypodermic, intramuscular, and intravenous medication. There are also chapters on blood transfusion, spinal puncture, and paracentesis.

Like most symposia there is great variation in the discussion of the numerous subjects. Dr Barach's contribution discussing the use of gases is particularly noteworthy. The book is well printed in easily readable type. If the subsequent volumes follow the same general plan as the first two there is no doubt that this work will become a valuable contribution.

J ROSCOE MILLER.

THE picture of a kindly, lovable, skillful surgeon with a happy faculty for making warring factions and individuals forget their differences and work in harmony, illuminates the pages of Finney's interesting, very readable and often amusing *Life of a Surgeon*².

The biographer in writing his own life story is handicapped (though not all biographers have been so restrained) by an innate modesty, and the desire not to say unkind or critical words about anyone, whether still living or long since passed into the great beyond. This restraint detracts perhaps from the color and vividness of a story which covers an important period in American medical and national history, and which brings to life again Princeton in the eighties, the Harvard Medical School and the

Massachusetts General Hospital of Maurice Richardson, Arthur Cabot, Homans and Porter, Fitz, Scudder and J. Collins Warren, the beginnings of the Johns Hopkins Hospital and Medical School, and, years later, the Great War. Great figures of the past troop by in an interesting array, and no medical man whose training and service began or ended during the half century of the author's active surgical career but will be interested in this panorama of events and personalities.

To the reviewer the most arresting pages are those in which the author pays tribute to Halsted, Welch, Osler, Thayer, and Walker—contemporaries and colleagues, with whom he lived and worked through so many stirring years. Here he can throw aside restraint and express himself with the enthusiasm and fervor of which he is capable. His portrayal of Halsted in particular makes "The Professor" live again, and persuades the reader that he can visualize and understand this distinguished teacher of surgery, though he never had the opportunity of studying under him or seeing him at work. Altogether the volume is a welcome addition to the annals of American surgery and will be treasured as such by all who read it.

SUMNER L KOCH

THE purpose of the authors, Meyer and Oscar Bodansky, in writing *Biochemistry of Disease*³ was to provide a "systematic presentation of the biochemical aspects of the various diseases, arranged according to clinical entities." To the reviewer's knowledge, there is no other book on biochemistry which is arranged and presented in this way, so that the biochemical aspects of any particular disease may be found under its specific heading.

The book is divided into eighteen chapters, each dealing with a particular group of diseases. It starts with a chapter on diseases of the blood, followed by one on diseases of the heart, a third on diseases of the digestive tract, while diseases of the kidneys and urinary tract are combined in one chapter as are diseases of the liver and biliary tract. Each of the endocrine glands is accorded a separate chapter. The last five chapters are devoted to diseases of bone, of muscle, disorders of metabolism and nutrition, and diseases of the nervous system.

By eliminating long theoretical discussions and including only those aspects of biochemistry which have a direct clinical application, the authors have made available a practical aid in diagnosis, prognosis, and treatment.

¹THE THERAPEUTICS OF INTERNAL DISEASES. Edited by George Blumer, M.A. (Yale) M.D. With the assistance of Albert J. Sullivan M.D. Vols. 1 and 2. New York and London: D. Appleton-Century Co., Inc., 1940.

²A SURGEON'S LIFE: THE AUTOBIOGRAPHY OF J. M. T. FINNEY. New York: G. P. Putnam's Sons, 1940.

They have presented a very thorough review of the literature, and extensive bibliographies at the end of each chapter enable the reader to consult the original sources. However being a review of the literature, it has the unavoidable shortcoming of being not completely up-to-date in certain instances.

Rarely are significant references omitted from the extensive bibliography.

The easy flowing style makes the presentation like the lectures of an experienced teacher. This volume should be popular with practitioners and students alike.

CORRESPONDENCE

VALUE OF RADIATION THERAPY IN THE TREATMENT OF CARCINOMA OF THE BREAST

To the Editor: A paper of mine entitled "The Value of Radiation Therapy in the Treatment of Carcinoma of the Breast" was published in volume 62, of SURGERY GYNECOLOGY AND OBSTETRICS, in April, 1936, p. 653. It has just been brought to my notice now that the averages given in the various tables in that paper are statistically invalid, since it would appear that for correct averages, count would have to be taken of the numbers of cases comprising

the various groups averaged. As I am neither mathematician nor statistician, I was not alive to this point, which must also have escaped the editorial staff.

Although this does not impair the interest of the other figures and observations, conclusions that depend upon comparisons of average figures are not proved. After all these years, it is difficult to make correction, but I should be happy if in the interests of scientific accuracy you could publish notes to this effect.

EXPERIMENTAL ANALYSIS OF THE GROWTH PATTERN AND RATES OF APPositionAL AND LONGITUDINAL GROWTH IN THE RAT FEMUR

LEON J. ARIES, M.D., Ph.D., F.A.C.S., Chicago, Illinois

THE problem of bone growth has been studied for centuries and to the present day is not completely understood. From the earliest records, information has been gathered from purely morphological studies. The chief advances in the knowledge of bone growth have been made using the physiological method of vital staining. The purpose of this study was to investigate experimentally the growth pattern and assess quantitatively the rates of growth in long bones by the method of vital staining.

REVIEW OF LITERATURE

The foundation of our knowledge of the mode of bone growth began in 1736 when John Belchier (16), an English surgeon, was entertained at a dinner by a calico printer. The entree was roast pig and a joint of this pig was served to Belchier. The pink, ruddy color of the bones of this pork aroused the scientist's curiosity and he asked his host about the origin of the pig. The calico printer, being an economical man, used the madder-soaked bran from his dye vats to feed his pigs. The pigs he then used to feed to his friends. Subsequently, Belchier fed madder root to a cock forcibly

From the Division of Surgery, Northwestern University Medical School. Awarded the Chicago Surgical Society Prize for Research Completed in 1940.

and it died in 16 days. This single result of the pink color of the fowl's bones, he reported to the Royal Society (3).

Henri Louis Duhamel fed madder to animals and then withdrew the dye. He observed that upon later sacrificing the animal, nearly all the redness was gone from the bone. This led him to believe that the stain was only temporary. When these bones were sectioned, he observed that the madder colored layer was covered and hidden by an unstained surface layer of bone laid down after the madder diet had been suspended. Duhamel then found by alternating madder diet with periods without madder he obtained red and white layers on the circumference of the bone. The last formed layer or plate was on the surface of the bone immediately under the periosteum. He concluded that bone grew as wood grew with superposition of layer upon layer. He also concluded that it was the periosteum that possessed the osteogenic function.

This method of vital staining with madder was not new although it was noticed by Belchier in 1736. It was known to the Greeks (11). The Egyptians brought madder from India where they learned the trick of combining it with calcium, aluminum salts, and polymerized fatty acids as mordants (18).

Madder is a powdered root of *Rubia cordifolia* in India and Central Asia. In Europe it is the *Rubia peregrina* (native wild plant) of England, Wales, and Ireland. The U S Dispensatory refers to it as *Rubia tinctorum* (23). The active principle of the madder root dye is alizarine and purpurin and its name was received from the trade name Levantine madder root (4). The dye occurs as a glucoside (ruberythric acid) in the roots in 2 to 4 per cent proportions and is obtained by fermentation or boiling with dilute acids. It is a reddish yellow powder insoluble in cold water and slightly soluble in boiling water. However it dissolves in hot alcohol, ether benzene glycerine, or glacial acetic acid.

Alizarine was isolated from madder by Robiquet and Cobin in 1827 (5). Graebe and Lieberman in 1870 showed that it was a glucoside of the anthraquinone type, 1-2 dihydroxyanthraquinone.

Perkin (17) 1870, found the sodium sulphate salt, alizarine red S which was more soluble and more stable than alizarine.

Alizarine has a varied tinctorial gradient depending on the hydrogen ion concentration of the medium. At hydrogen-ion concentration 5 it is yellow at hydrogen ion concentration 5 to 6.8 red and at hydrogen-ion

TABLE I.—EXPERIMENTAL HISTORY OF 52 ALBINO RATS GIVEN INJECTIONS OF ALIZARINE RED S FROM 11 TO 299 DAYS OF AGE

Group No	Arbitrary age range of animals in days	Number of animals allocated to each group	Age in days when injected	Interval between injections in days	Age when sacrificed
	10-30	20	8-4-18-66	7-4-97 90-11	32-62-66 67-67-75
	30-60		12-14-26-38 37	16-14-66 20-12-37	64-66-66 67-67-75
	60-90	14	1-2-77-78 84-87-93-99	1-2-84-85 41-44-4	90-91-97 97-100 101-104
	90-120		108-109-108 109-109-109 143-143	0-4-20 27-27-20 41-46	1-13 10-113 130-146 154-157 170-170
5	30-90		162-162-173	0-9-30 21-23-24	170-170 169
6	90-204		102-112-100	1-2-30 12-12-100	100-100 200-200

concentration greater than 6.8 it is purple (4). The younger the age of the animal injected, the deeper is the color of the stain in the bones and teeth while old animals take the stain poorly or not at all. Thus, there is a selective staining of bone and teeth which are growing and calcifying at the time of injection.

Hoffman (12) in 1939 demonstrated that the staining effect of alizarine red S in bones is dependent upon the hydrogen-ion concentration value of the colloidal matrix at moment the calcium precipitates to its earthy state.

Schour and Hoffman (13, 19-22) measured the appositional growth of the incisor and molar teeth in the rat, as demonstrated by alizarine red S. These workers injected the rat with alizarine red S at varying intervals and measured the amount of appositional growth over that given period. Their work opened a new field of research on growth of teeth and bones and directly suggested a similar study on rat femur.

METHOD AND MATERIALS

This study is based on the examination of 180 albino rats ranging from 7 to 304 days of age. Intraperitoneal injections of a 2 per cent isotonic alizarine red S solution, color index No. 034, were given at intervals of 7 to 101 days. The pharmacological dosage was

experimentally found to be approximately 100 milligrams per kilogram (Hoffman and Schour, 19) The macroscopic and microscopic measurements were based on 52 animals (Tables I, II, III, and IV) Intravenous injection allowed for too rapid excretion of the dye before it could be deposited in the ossifying bone

Number of injections On the basis of preliminary trial animals, it was found advisable to limit the number of injections to one or two for each animal since more than two lines caused confusion as to which injection produced which line For convenience, the animals were allocated into incremental age groups depending upon the days on which they were injected (Table I)

Dissection and the preparation of microscopic sections The usual method of making microscopic sections of bone for histological study by decalcification in acid could not be employed in this experiment since the red to purplish effect of the alizarine red S in the bone is decolorized Gross specimens were preserved in 10 per cent formalin to which magnesium carbonate had been added After the bone was cleaned of all muscular and tendinous attachments, cut sections were prepared at the following levels (a) through the neck and head, (b) transversely through the shaft, distal to the lesser trochanter, (c) transversely through the diaphysis, and (d) longitudinally, midsagittal mediolateral sections (Figs 1 and 2)

The bone was cut with a 0.5 millimeter jeweler's saw blade which was mounted in an appropriate frame One surface of the cut section was ground smooth on a circular fine grade carborundum stone attached to a laboratory lathe This section was dehydrated in alcohol and treated with acetone The smooth surface was fixed to the flat ground facing of a cork in cellulose cement The cement served as an embedding medium and to attach the section to the cork When the cement was completely set (4 hours), the exposed surface was ground to a thickness of 20 to 50 microns While being ground, the bone was continuously cooled and washed free of debris by a stream of water passing through a brush placed against the stone Final polishing of the section was completed on a hard Arkansas stone

The bone was removed from the cork by immersion in acetone Several changes in fresh acetone were necessary to free the sections of excess cellulose cement The sections were then dried and cleared for 24 hours in xylol and mounted in gum dammar It was found that the red stain faded and disappeared in several weeks from sections which were mounted in balsam One half of the longitudinal section of the femur was ground and mounted as described while the opposite half was immersed in xylol for clearing The cleared bones were examined with the aid of a binocular dissecting microscope while suspended in the clearing solution The red stain could be studied from a three dimensional aspect

Method of examination Gross specimens were measured for length and diameters overall with a Boley gauge Readings were made correctly to 1/100 of a millimeter

Microscopic studies of the ground sections were made under the 32 and 16 millimeter objectives A vernier filar micrometer eyepiece which was calibrated to a standard micrometer stage for the microscope and lenses, was used to make the measurements between the injection effects of the alizarine red S Measurements were made in microns and were calculated correctly to within the first decimal place

Measurements were made at the levels shown in Figures 1 and 2 The mean values, standard deviations, and error of the mean were calculated for the specific levels of animals within specific age groups (Table I)

The measurements of the means for each animal were plotted against time (Figures 5, 6, 7, 8), both arithmetically and logarithmically

FINDINGS

Gross observations Gross examination revealed a diffuse, purplish-red stain of the femur in animals injected with alizarine red S from birth to 15 days of age Animals injected at 15 days of age and sacrificed at 30 to 60 days of age presented a diffuse, purplish-red stain in the metaphyseal portions of the bone and a colorless diaphyseal bone as well as a colorless subcapital segment The junction of the colorless diaphysis with the shaft showed an intensely stained band which encircled the bone at that level (Fig 3, left) The longitudinally

Fig Photomicrographs of transverse ground sections and levels at which they are made through the femurs of alluminated rats. *A* Longitudinal through head and neck and obliquely through the shaft distal to the greater trochanter. *B* Shaft, just distal to the lower trochanter. *C* Diaphyseal end of shaft.

cut section (Fig 2) of the bone presented a diffuse red stain in the medullary cavity, but the sharp differentiation between colorless diaphysis and stained shaft was not seen as a sharp line and faded gradually toward the distal end.

The circumferential colored lines on the surface of the cortex in the shaft of the bone were parallel to the epiphyseal plate and varied in their distance from the epiphyseal plate in

approximately direct relation to the number of days intervening between injections. The animals which were given injections at varied intervals presented parallel colored rings about the shaft, the distance between which was the amount of longitudinal growth at the diaphyseal ends of the bone for that interval.

The longitudinal midsagittal sections (Fig 4) presented oblique red lines extending from the medulla of the shaft outward and toward

the epiphysis (Fig 3 and 4) to end tangentially at the surface of the bone with the parallel lines mentioned. This would be at the epiphysis if the animal were injected and sacrificed within a few days. When 10 to 30 days elapsed between an injection and the time the animal was sacrificed, these oblique red lines were found at a distance away from the epiphyseal plate and ended at the periosteal surface red line (Fig 4). This arrangement of a circular base with oblique lines beginning at the cortical margin and extending away from the epiphysis and medially formed a red truncated cone. The cleared femurs of animals which had been given one injection presented this picture in three dimensions when examined with a binocular dissecting microscope. When a second injection was given 30 days later the oblique red lines were found epiphyseally to the first line and were parallel to them. These oblique lines ended at the periosteal surface of the cortex where the red circular lines were found. The perimeter of the base of this cone formed the circumferential lines seen on the surface of the cortex (Fig 3). Each succeeding injection line was found epiphyseally to the previous one in the form of one cone within another. The base was the epiphyseal plate but as more bone was deposited, the legs and the perimeter of the cone (Fig 4) remained in the shaft as fixed planes. The base remained as the epiphyseal plate and did not take the alizarine stain.

Subsequent injections formed new cones which were seen to dovetail within the cones formed by the previous alizarine red S effects. The epiphyseal plate was now found to have receded from the levels of the initial alizarine red S rings (on the surface of the bone) and was approximately parallel to them.

The neck. Longitudinal sections through the neck (Fig 1, A) included an oblique section through the shaft and lesser trochanter. The oblique endosteal red lines passed from the marrow cavity of the neck upward and outward toward the capital epiphysis. The periosteal deposit was found about the neck and was continuous with the red line in the trochanter and shaft (Fig 1, A and 4). A morphological arrangement of the alizarine red S lines, similar to that of the distal end of the

Fig 2 D, Longitudinal mid-sagittal section through shaft of the femurs of alizarinated rats. E, Mediolateral. F, Anteroposterior.

femur, existed in the neck. Similar truncated cones appeared superposed one within another excepting that the base was proximal while in the condylar end of the femur the base of the cone was distal.

Fig. 3. Photograph of the femur of 78 day old rat showing the effect of one injection of alizarine red S given at 87 days of age. Left, midsagittal longitudinal section of left femur showing alizarine red S effect in cortex. Right, Outer surface of the cortex of the right femur showing the alizarine red S effect at the proximal and distal end.

Fig. 4. Longitudinal section through femur showing the alizarine red S effects in 70 day old animal. Solid line, first injection at 60 days of age. Broken line, second injection at 70 days of age.

Periosteal growth. Concomitant with the longitudinal growth of bone there was seen a subperiosteal deposition of bone about the entire shaft. This subperiosteal deposition of bone showed the alizarine red S effects. When viewed in cross section, circular red rings were seen to parallel the periphery of the bone. Cross sections through the shaft at the subtrochanteric level (Fig. 1 B) showed circular red lines in the cortex. The number of concentric lines at this level was directly representative of the number of injections given.

Transverse sections through the diaphysis presented three different findings dependent upon (1) level of diaphysis through which section was made (2) number of injections and (3) interval of time between injections.

When one injection was given one or two circular lines were found. When two injections

were given, two, three, or four concentric red rings were seen (Fig. 4 A B C). The distance between the lines was not regularly equal as those found in the subtrochanteric region of the shaft. To clarify the discrepancy in the number of circular red lines found in the diaphysis as compared with the number of injections given, it was necessary to restudy the cleared sections. The junction of the red line of the cone on the inner surface of the shaft with the periosteal deposit showed two lines on cross section (Fig. 5 C). The solid black line indicates size of bone at time of first injection. Broken line at second injection.

Haversian bone. The walls of the vascular channels in the haversian systems showed the

Fig 5 Graph showing total lengths in millimeters and total longitudinal increments as shown by alizarine red S effects in the femurs of 52 albino rats from 11 to 364 days of age (From Table II)

alizarine red S effects in the arrangement of concentric rings. The concentric lamellae of the bone cells were parallel to these red rings. Bone growth within the haversian systems occurred as a result of deposition of new bone on the wall of the vascular channel and

caused a diminution in the diameter of the channel.

Intervals from 10 to 300 days showed that the daily rates of growth decelerated with age in crease (Table III, Fig. 6). These measurements closely coincided with similar data on longitudinal growth of the femur as shown by Donaldson.

Microscopic Measurements which were made between the last two alizarine red S effects for specific age groups (Table I) showed that the increase at either the distal or the proximal ends alone was not equivalent to the total increase over-all for the femur at any given period. The sum, however, of the vertical increases at the distal and proximal ends closely coincided with the total increase over all (Table II, Fig. 5).

Rates The daily rates of growth, both experimental and calculated as shown by the alizarine red S effects decelerated with age increase. The latter assessments of daily rates (sum of distal plus proximal) closely coincided with the calculated rates which were obtained from the curve on measurements of length over-all (Table II, Fig. 5).

Gradients From the plotting of the decelerating rates on semilogarithmic graph paper (Fig. 6) it is evident that a gradient of growth

exists in the longitudinal growth of the rat femur. Logarithmic plotting of the total increments (Fig 7) resulted in a straight line graph and also makes it evident that a gradient of growth exists (Huxley)

Subperiosteal growth Measurements between injection effects in cross sections below the lesser trochanter showed that the distance between any two red lines was the amount of bone deposited for the given period at that level. The rates of growth were seen to be greater on the anterior than on the posterior surface (Table IV, Fig 8). The growth of bone beneath the periosteum also decelerated with age increase for anterior and posterior surfaces (Table IV, Fig 8).

Statistical evaluation on the basis of 1,034 trial measurements. The standard deviation was found to be 0.990 with a mean error of ± 0.249 .

ANALYSIS OF STUDY

Pattern of growth Textbooks of histology and embryology (1, 6, 15) have, to the present time, described the longitudinal growth of bone to take place by apposition at the diaphyseal side of the epiphyseal plate in the form of lines parallel to the epiphyseal plate. Our findings show the longitudinal apposition to be on the endosteal surface in the form of a cone whose base is the epiphyseal plate (Fig 4, A). Multiple injections of alizarine red S

Fig 7 Graph showing the logarithmic plotting of the increments of longitudinal growth in the femur of 52 albino rats from 11 to 304 days of age

have demonstrated that the appositional process results in a series of cones, each succeeding injection effect dovetailed within the previous. From a three dimensional aspect, it can be demonstrated that each successive endosteal deposit at the base (epiphyseal plate) possesses a greater perimeter than the previous one, and

consequently produces a flare at the epiphysal line. The latter accounts for the increasing flare at the epiphysal end of the bone with advance in age. *As a result there is a tubularization pattern in the growth of the long bones.*

The growth of the periosteal bone would, off hand, appear to limit the pattern of bone to a straight cylinder with parallel walls. However the periosteal growth follows the pattern of the internal cone and serves to increase the

width of the cortex with increase in age. Preliminary assessments of periosteal growth on the same material have shown that the rate of growth is greater in the region of the shaft near the subtrochanteric area than at the diaphysis. Hence, approximately the total diameter of the bone at the epiphysal line is due to the flare of the legs of the cone within the diaphysis (Fig 4). This morphological pattern which is found at the distal end of the femur is also seen in the neck, though quantitatively to a lesser degree in the latter. The endosteal arrangement in cones as found in the femur was also found in the other long bones.

Mechanics of growth pattern. The structural growing pattern of the femur consists of two series of truncated cones with bases facing away from the shaft at both ends. The tibia at its proximal end presents a pattern similar to and approximately a mirror image of the growth pattern of the distal end of the femur.

Hence, on either side of the knee joint there is a series of truncated cones whose bases are separated only by the epiphysal of the femur and tibia, respectively. Weight is transmitted from the shaft of the femur to its wide distal base and received by the corresponding cap at the proximal end of the tibia.

Such an arrangement is one of the strongest geometric configurations known to engineering for weight support and serves for balanced equilibrium in force distribution. Columns with a cap and base are commonly employed by architects to support buildings.

Model. It was necessary to construct a transparent model of the femur to clarify in our minds the three dimensional effects of alizarine red S. The model was prepared by compressing a mixture of the monomer and polymer of methyl methacrylate (Lucite) in a negative stone mold encased in a steel flask.

Lines of arrested growth. The peripheral base of each cone explains the so called Harris "lines of arrested growth" (10) Harris has described these lines seen on x-ray films. Brash has superposed serial x ray films of Harris and has attempted to explain tubularization of bone on this basis. At present we are utilizing the alizarine red S method of vital injections to experimentally elucidate the significance of these "lines of arrested growth."

Outlook The method for study of normal bone growth as described in this investigation may be readily employed in experiments dealing with studies (1) involving growth stimulating or growth arresting substances, (2) healing of fractures, (3) bone grafting, and (4) the fate of grafts, and other problems related to normal and pathologic conditions in bone

SUMMARY AND CONCLUSIONS

1 This study was based on the gross examination and microscopic study of the ground longitudinal and cross sections of the femurs of 52 albino rats, 10 to 305 days of age, which were given multiple intraperitoneal injections of a 2 per cent solution of alizarine red S (100 milligrams per kilogram) at specified intervals. Quantitative assessments were made of the rates of longitudinal and subperiosteal growth. The pattern of morphological growth was analyzed as a result of the alizarine red S effects

2 Findings show

a The longitudinal growth of long bones is a result of superposition of serial cones within the diaphyseal portion of the shaft, the bases of which cones are the epiphyseal plate at any given period

b The periosteum deposits bone on the circumferential surface of the shaft only and does not contribute toward the longitudinal growth of the femur

c The distal end of the femur grows faster than the proximal end (neck). The sum of the growth at both ends accounts for the total increase in length

d The longitudinal growth and the growth in width follows a growth gradient—the rates decelerating with increase in age

e Haversian system growth as shown by the alizarine red S effects occurs on the surfaces of the vascular canals. The red rings were seen to parallel the haversian lamellae. The diameter of the canals during appositional growth decreases with age

3 The morphological pattern of the tubularization of bone is compared to mechanical

supports as utilized in engineering and bears out the application of this mechanical arrangement to the knee joint

4 Suggestions are offered for further investigation on normal and pathological studies on bone, utilizing the vital injections of alizarine red S

THE TENSILE STRENGTH OF SUTURED SKIN WOUNDS DURING HEALING

THOMAS W. BOTSFORD M.D., Boston, Massachusetts

THIS investigation was undertaken to study the healing of uncomplicated and complicated incised skin wounds in animals. In these experiments the degree of healing was measured by determining *in vivo* the tensile strength of the wound by the use of an apparatus which will be described later. Since the holding power of an incised wound, after the sutures have been removed, can depend upon little else than the degree of fibroplasia, the tensile strength should give an excellent index to the stage of healing. Uncomplicated incised wounds were observed to obtain a normal standard for this method of measurement. Wounds were opened and reclosed to obtain information on the value of secondary suture. Chromic catgut and silk were compared in another series of wounds, and the effect of avirulent bacteria as wound contaminants was studied. Finally observations were made upon the value of splenic extract and embryonic extract in the healing of incised wounds of the skin.

Howes, Sooy, and Harvey (6) were the first to study wound healing as reflected by wound tensile strength. They made wounds in the skin, fascia, muscle, and stomach of dogs. The animals were sacrificed at varying intervals; the wounds were excised and their tensile strength determined with a thread-testing machine. Later Harvey attacked the problem by making wounds in the stomach of the rat, and found the strength of the wound by inflating the viscus with air. In those experiments the workers demonstrated a standard curve for wound healing, which shows a quiescent period for the first 4 to 6 days, followed by a rapid gain in wound tensile strength until 10 to 14 days, when maximal wound strength is obtained. The latter stage is termed the phase of fibroplasia. It is of interest that Car-

rel had reached somewhat similar conclusions in his observations upon the diminishing surface area of open wounds.

METHOD

A total of 77 adult guinea pigs and 11 adult dogs was used. The former were given all they could eat of a diet consisting of one-third whole bran, one-third cut hay, and one-third bruised oats. Green cabbage and water were given in unlimited quantity. The dogs received a stock diet of meat and scraps, with water as desired. The diets contained adequate carbohydrate, fat, protein, and vitamins for the requirements of these animals.

All wounds were made under ether anesthesia after preparation of the shaven skin with ether and iodine. Aseptic operating room technique was rigidly adhered to and the wounds were dry before suturing. In the guinea pigs, two 3 centimeter wounds were made in each animal, one on each side of the spinal column approximately 1.5 centimeters from and parallel to it. Eight vertical 4 centimeter incisions were made on the abdomen of the dogs, distributed so that their blood supply was approximately the same. All wounds were through the skin and subcutaneous tissue only and were closed with a single layer of interrupted untreated 6/8 pound tensile strength, silk sutures. The silk was sterilized by autoclaving 5 minutes at 20 pounds pressure. At end of operation a dry sterile dressing was applied.

The wounds were tested on various days after operation. In each guinea pig both wounds were tested at the same time and two more wounds were tested on the same day in each dog. When the wounds were to be tested, the animals were anesthetized with ether and the dressing was removed. A Mikkel skin clip 3 millimeters wide, or a small towel clip was then firmly clipped into the skin on each side at right angles to the approximate midpoint on the wound and about 1 centi-

Fig 1 Tensiometer for opening skin wounds, with spring balance
 Fig 1a Tensiometer with pulley and mercury bucket

meter from it. The wound tensile strength testing apparatus pictured in Figure 1 was used. The hooks *A* and *B* (Fig 2) were inserted through the loops of the skin clips. The wound sutures were now gently removed. The screw handle *C* (Fig 2) was then slowly turned. This exerted constantly increasing tension upon the *A* side of the wound, whereas the *B* side remained fixed. The tension at which the wound gave was read directly from the spring balance *D* (Fig 2). For wounds over a tensile strength of 1000 grams, a cord, a pulley, and a small bucket were substituted for the spring balance (Fig 1a). Mercury was dropped into the bucket from a burette, and the total weight necessary to open the wound was easily calculated. When the test was finished, the wound was reclosed with sterile Michel skin clips. Infected wounds were not used except in the wound contaminant experiment. Whether this method of determining wound tensile strength *in vivo* is as accurate as that done with excised specimens is debatable. However, when wounds of similar size are tested in the same fashion each time,

the error should be constant and the results consistent and accurate for comparison in a series. A total of 252 wounds was thus tested.

RESULTS

Group I In this group the wounds were all uncomplicated, incised wounds sutured with fine silk. The curve of wound healing for 65 such wounds in guinea pigs is shown in Figure 3. The progress of healing, as measured by wound tensile strength, is slow but definite until the fourth day, thereafter there is a rapid rise in tensile strength until the tenth day, when the tensile strength remains more or less constant until the eighteenth day, which was the limit of the experiment. It is likely that in a given animal with 2 wounds made at the same time, the healing of the wounds should parallel each other, provided the blood supplies are equal and that infection is absent. In a series of 14 guinea pigs, each with two wounds, 8 of the animals had wounds that had tensile strengths within 100 grams of each other, while 6 showed a difference of 100 to 200 grams.

Fig. 2. Illustration of the use of the tensiometer

Fig. 3. Tensile strength of skin wounds in guinea pig during healing. —x, mean curve ---, individual wound strength.

As seen in Figure 3 the animals tested on any particular day showed considerable variation in the tensile strength of their wounds, and this variation tends to increase as the mean tensile strength becomes greater. Thus, on the eighteenth day the readings varied from 350 grams to 850 grams, the range being 500, while on the first day the range was only 221 (9 gm. to 240 gm.) It might be anticipated that the range would be approximately proportional to the mean, and for this reason the coefficient of variation was calculated this is the standard deviation S divided by the mean M . As the number of animals tested on any particular day was few the standard deviation was computed for

each day by the formula $S = \sqrt{\frac{\sum (\lambda - M)^2}{n-1}}$

where λ represents the separate readings λ ——— \bar{X} and n equals the number of readings. The average value of the coefficient

of variation so calculated was found to be 0.71. An estimate was also made of the coefficient of variation for multiple wounds in single guinea pigs from animals that had two wounds each. The average value was 0.24. This is much less than that found for wounds in different animals, and it suggests that in guinea pigs, individuals show considerable differences with regard to wound healing which are much in excess of those shown by a single animal.

The curve for healing in 27 incised skin wounds in dogs is shown in Figure 4. The curve is of special interest for it is very similar to that reported by Howes, Sooy and Harvey from the determination of the strength of excised skin wounds in dogs. The gain in tensile strength is relatively slow until about the sixth day when there is a rapid rise until the eighth day and then a gradual gain in strength until the sixteenth day. Eight wounds in a single dog were tested in pairs at 4-day intervals for 16 days. None of the wounds was infected, and grossly they appeared much the same however the differences in the strengths of the wounds were striking (Table I). At each test, except the 4-day test, there was a difference in tensile strength ranging from 544 grams to 884 grams.

BOTSFORD TENSILE STRENGTH OF SUTURED SKIN WOUNDS

Fig 4 Tensile strength of skin wounds in dogs during healing
x—x, mean curve, individual wound

Fig 5 Tensile strength of resutured wounds. All retests performed 7 days after the first test. Black columns, original strength of wound, white columns, strength of second test.

The variability in a single dog is of much the same order as in a single guinea pig, but differs from animal to animal. The coefficient of variation for wounds in a single animal was calculated from four pairs of wounds in one dog and was found to be 0.17. As this is derived from eight wounds, the standard error is considerably over 0.04 and does not differ significantly from the corresponding value of 0.24 found for guinea pigs. The coefficient of variation for different dogs was calculated to be 0.22, which is much less than the value for guinea pigs of 0.71. This means that the relative variation of tensile strength of wounds in dogs is only about one-third that found in wounds in guinea pigs. It is to be remembered that the actual strength of wounds in dogs is about five times that of guinea pigs, so that the range of tensile strength in grams is actually greater in the dog. It is, however, the relative strength that is important from a practical point of view and this is brought out by the coefficient of variation.

It is obvious that in interpreting the results of any study of wound healing, this variation in the healing of multiple incised wounds in single animals and from one animal to another must be considered. It also follows that wound healing varies with species.

A number of wounds in guinea pigs, reclosed after the original wound test, were retested 7 days after the secondary closure of the wounds. The gains in wound strength over the original strength after secondary wound closure are shown in Figure 5. This demonstrates that resutured wounds are stronger. In only two wounds (not shown on the chart) were the tensile strengths less than the original, both of these wounds were infected. The increase in tensile strength in these secondarily closed wounds was great, and did not bear any relation to the original strength of the

TABLE I—VARIATION OF TENSILE STRENGTH IN MULTIPLE WOUNDS OF A SINGLE

	6	2250		
16	7	3006	544	
	8	1500		

Fig. 2. Illustration of the use of the tensiometer

As seen in Figure 3 the animals tested on any particular day showed considerable variation in the tensile strength of their wounds, this variation tends to increase as the tensile strength becomes greater. Thus, on the eighteenth day the readings varied from 350 grams to 850 grams, the range being while on the first day the range was only 19 gm. to 240 gm.) It might be anticipated that the range would be approximately proportional to the mean, and for this reason the coefficient of variation was calculated this is the standard deviation divided by the mean M . As the number of

readings on any particular day was n , the standard deviation was computed for

$$S = \sqrt{\frac{\sum (x - M)^2}{n - 1}}$$

where x represents the separate readings $\sum x$ divided by n equals the number of average value of the coefficient

Fig. 3. Tensile strength of skin wounds in guinea pigs during healing. —, mean curve; •, individual wound strength.

of variation so calculated was found to be 0.71. An estimate was also made of the coefficient of variation for multiple wounds in single guinea pigs from animals that had two wounds each. The average value was 0.24. This is much less than that found for wounds in different animals and it suggests that in guinea pigs individuals show considerable differences with regard to wound healing which are much in excess of those shown by a single animal.

The curve for healing in 27 incised skin wounds in dogs is shown in Figure 4. The curve is of special interest for it is very similar to that reported by Howes, Soov, and Harvey from the determination of the strength of excised skin wounds in dogs. The gain in tensile strength is relatively slow until about the sixth day, when there is a rapid rise until the eighth day, and then a gradual gain in strength until the sixteenth day. Eight wounds in a single dog were tested in pairs at 4-day intervals for 16 days. None of the wounds was infected, and grossly they appeared much the same, however the differences in the strengths of the wounds were striking (Table I). At each test, except the 4-day test, there was a difference in tensile strength ranging from 544 grams to 883 grams.

Fig 4 Tensile strength of skin wounds in dogs during healing x-x, mean curve, , individual wound strengths

The variability in a single dog is of much the same order as in a single guinea pig, but differs from animal to animal. The coefficient of variation for wounds in a single animal was calculated from four pairs of wounds in one dog and was found to be 0.17. As this is derived from eight wounds, the standard error is considerably over 0.04 and does not differ significantly from the corresponding value of 0.24 found for guinea pigs. The coefficient of variation for different dogs was calculated to be 0.22, which is much less than the value for guinea pigs of 0.71. This means that the relative variation of tensile strength of wounds in dogs is only about one-third that found in wounds in guinea pigs. It is to be remembered that the actual strength of wounds in dogs is about five times that of guinea pigs, so that the range of tensile strength in grams is actually greater in the dog. It is, however, the relative strength that is important from a practical point of view, and this is brought out by the coefficient of variation.

It is obvious that in interpreting the results of any study of wound healing, this variation in the healing of multiple incised wounds in single animals, and from one animal to another, must be considered. It also follows that wound healing varies with species.

Fig 5 Tensile strength of resutured wounds. All re-tests performed 7 days after the first test. Black columns, original strength of wound, white columns, strength of second test.

A number of wounds in guinea pigs, reclosed after the original wound test, were retested 7 days after the secondary closure of the wounds. The gains in wound strength over the original strength after secondary wound closure are shown in Figure 5. This demonstrates that resutured wounds are stronger. In only two wounds (not shown on the chart) were the tensile strengths less than the original, both of these wounds were infected. The increase in tensile strength of these secondarily closed wounds varied a great deal, and did not bear any definite relation to the original strength of the wound.

TABLE I — VARIATION OF TENSILE STRENGTH IN MULTIPLE WOUNDS OF A SINGLE DOG

Post operative day of wound test	No of wounds in dog	Tensile strength of wound in grams	Difference in grams	Coefficient of variation
4	1	350	50	09
	2	400

	8	2550		

Fig. 2. Illustration of the use of the tensiometer.

As seen in Figure 3 the animals tested on any particular day showed considerable variation in the tensile strength of their wounds, and this variation tends to increase as the mean tensile strength becomes greater. Thus, on the eighteenth day the readings varied from 350 grams to 850 grams the range being 500, while on the first day the range was only 222 (10 gm. to 240 gm.) It might be anticipated that the range would be approximately proportional to the mean, and for this reason the coefficient of variation was calculated this is the standard deviation S divided by the mean M . As the number of animals tested on any particular day was few the standard deviation was computed for

each day by the formula $S = \sqrt{\frac{\sum (V_x - M)^2}{n - 1}}$

where V_x represents the separate readings λ — — — λ and n equals the number of readings. The average value of the coefficient

Fig. 3. Tensile strength of skin wounds in guinea pigs during healing. —, mean curve. ---, individual wound strengths.

of variation so calculated was found to be 0.71. An estimate was also made of the coefficient of variation for multiple wounds in single guinea pigs from animals that had two wounds each. The average value was 0.24. This is much less than that found for wounds in different animals, and it suggests that in guinea pigs, individuals show considerable differences with regard to wound healing which are much in excess of those shown by a single animal.

The curve for healing in 37 incised skin wounds in dogs is shown in Figure 4. The curve is of special interest for it is very similar to that reported by Howes, Sooy and Harvey from the determination of the strength of excised skin wounds in dogs. The gain in tensile strength is relatively slow until about the sixth day when there is a rapid rise until the eighth day and then a gradual gain in strength until the sixteenth day. Eight wounds in a single dog were tested in pairs at 4-day intervals for 16 days. None of the wounds was infected, and grossly they appeared much the same however the differences in the strengths of the wounds were striking (Table I). At each test, except the 4-day test, there was a difference in tensile strength ranging from 544 grams to 884 grams.

Fig 8 Tensile strength of skin wounds in guinea pigs, sutured with silk and with catgut. —, silk mean, o—o, catgut mean.

wounds sutured with catgut and silk, respectively, are real. This is further supported by the fact that of the 11 animals examined from the fourth day onward, everyone agreed, in that the wound closed with silk was superior in strength to that sutured with catgut. Assuming equal chances of catgut or silk appearing superior in any animal, the chance of the whole 11 agreeing is $1/2^{10}$ or approximately 1 in 1000. The conclusion would seem justified that, after 4 days, skin wounds sutured with silk were less easily ruptured than those sutured with catgut in guinea pigs.

With regard to the fourth day (Fig 8), the observations are limited to 2 animals, but in both of these the catgut wound was stronger than the silk wound. Further examination of the figures suggests that this result is in fact a significant one, but it is inadvisable to be dogmatic in view of the small number of animals.

Group IV Recent reports by Nielson and Waugh have indicated that an embryonic extract developed by Dr Albert Fisher, of the Carlsberg Biological Institute, Copenhagen, is of value in accelerating the healing of open surface wounds both in man and in experimental animals. These workers measured the diminishing area of the open wounds, and, by

Fig 9 Tensile strength of skin wounds in dogs, treated with epicutan. —, mean of wounds treated with epicutan, o—o, mean of control wounds, ∞, individual wound strengths.

using du Noüy's mathematical equation by which the rate of healing might be expressed and its normal course predicted, concluded that the preparation accelerated the healing by about 30 per cent. The preparation¹ of embryonic extract referred to is known as "epicutan" and is a protein derivative of embryonic tissue absorbed in kaolin powder (8).

Because of the foregoing work, it was thought to be of interest to determine the effect of epicutan upon wound tensile strength. Accordingly, the preparation was dusted into 12 wounds in dogs. There was one control wound for each treated wound. When the results are considered in Figure 9, it is at once apparent that epicutan has no appreciable effect upon wound tensile strength. The preparation is recommended for open surface wounds, and it might be said that this is not a fair trial.

Group V An extract of animal spleen was prepared by Dr J N Davidson, physiology department, University College, Dundee. This splenic extract was applied to wounds in guinea pigs and dogs to determine whether it had any effect upon the acceleration of wound healing.

¹Manufactured by Messrs Lundbeck of Copenhagen under direction of Dr Fisher.

Fig. 6. Tensile strength of skin wounds in guinea pigs, contaminated with *Staphylococcus albus*. — wounds inoculated o—o, control wounds, + posth. culture from wound.

It is worth noting that the strongest wounds in the guinea pigs were in this group of wounds retested seven days after being opened.

Group II Because of the interest in causes of postoperative wound complications, the effect of avirulent bacteria as wound contaminants was studied. While these organisms usually do not cause wound suppuration, it was desired to find out if they have any effect upon the wound tensile strength. One wound in each of 13 guinea pigs was heavily inoculated with a 48 hour old dextrose broth culture of *Staphylococcus albus*, and in 8 guinea pigs a similar culture of *Bacillus subtilis* was used. These organisms were cultivated from room air. There was one control wound in each animal. Cultures were taken before operation from the skin and again from each wound as it was opened by the tensiometer. In 5 instances the pre-operative skin culture was positive for *Staphylococcus aureus*. Only one wound in this group became infected and that was a control wound. A mixed culture of *Staphylococcus aureus* and *Bacillus proteus* was obtained. In both groups of guinea pigs,

Fig. 7. Tensile strength of skin wounds in guinea pigs, contaminated with *Bacillus subtilis*. — wounds inoculated with *Bacillus subtilis*, o—o, controls; + posth. culture from wound, I, infected control wound.

the contaminant was recovered by culture from the inoculated wound on every day from the first to the fourth day thereafter no organisms could be obtained by culture. In both the experiments the inoculated wounds were slightly stronger than the control wounds, although there was not much to choose between the control and contaminated wounds (Figs. 6 and 7). It would appear that mild wound infection has a favorable effect upon wound tensile strength. It is of interest to note the low tensile strength of the infected control wound (Fig. 7).

Group III In a series of 14 guinea pigs, one wound was sutured with two interrupted, No. 00 (Bnt. Pharm.) 20 day chronic catgut sutures, while another wound in each animal was closed with two interrupted fine silk sutures. When the results given in Figure 8 are compared it is suggested that the catgut is slightly superior to the silk for the first 4 days but inferior on subsequent days. In the light of the great variability of wound healing in normal wounds, it would seem desirable to examine the figures from a statistical point of view. By use of the coefficient of variation (0.24) for two wounds in 1 animal an estimate was made of the standard error of the differences of the two wounds in each animal, and from this the probability P was obtained that the differences greater and equal to the observed ones should have occurred by chance. The value, P however was found to be less than 1/50 which confirms the conclusion that the differences between the

Fig 8 Tensile strength of skin wounds in guinea pigs, sutured with silk and with catgut. —, silk mean, o-o, catgut mean.

wounds sutured with catgut and silk, respectively, are real. This is further supported by the fact that of the 11 animals examined from the fourth day onward, everyone agreed, in that the wound closed with silk was superior in strength to that sutured with catgut. Assuming equal chances of catgut or silk appearing superior in any animal, the chance of the whole 11 agreeing is $\frac{1}{2^{10}}$ or approximately 1 in 1000. The conclusion would seem justified that, after 4 days, skin wounds sutured with silk were less easily ruptured than those sutured with catgut in guinea pigs.

With regard to the fourth day (Fig 8), the observations are limited to 2 animals, but in both of these the catgut wound was stronger than the silk wound. Further examination of the figures suggests that this result is in fact a significant one, but it is inadvisable to be dogmatic in view of the small number of animals.

Group IV Recent reports by Nielson and Waugh have indicated that an embryonic extract developed by Dr. Albert Fisher, of the Carlsberg Biological Institute, Copenhagen, is of value in accelerating the healing of open surface wounds both in man and in experimental animals. These workers measured the diminishing area of the open wounds, and, by

Fig 9 Tensile strength of skin wounds in dogs, treated with epicutan —, mean of wounds treated with epicutan, o-o, mean of control wounds, o-o with dot, individual wound strengths.

using du Noüy's mathematical equation by which the rate of healing might be expressed and its normal course predicted, concluded that the preparation accelerated the healing by about 30 per cent. The preparation¹ of embryonic extract referred to is known as "epicutan" and is a protein derivative of embryonic tissue absorbed in kaolin powder (8).

Because of the foregoing work, it was thought to be of interest to determine the effect of epicutan upon wound tensile strength. Accordingly, the preparation was dusted into 12 wounds in dogs. There was one control wound for each treated wound. When the results are considered in Figure 9, it is at once apparent that epicutan has no appreciable effect upon wound tensile strength. The preparation is recommended for open surface wounds, and it might be said that this is not a fair trial.

Group V An extract of animal spleen was prepared by Dr. J. N. Davidson, physiology department, University College, Dundee. This splenic extract was applied to wounds in guinea pigs and dogs to determine whether it had any effect upon the acceleration of wound healing.

¹Manufactured by Messrs. Lundbeck of Copenhagen under direction of Dr. Fisher.

Fig. 9. Tensile strength of skin wounds in guinea pigs, treated with splenic extract — wounds treated with splenic extract o—o, control wounds

A consideration of the results from wounds in 8 guinea pigs (Fig. 10) shows that there was little difference between the treated and the untreated wounds, except that the splenic extract treated wounds did reveal a tendency for a gain in tensile strength to be more rapid than in the control wounds. The treated wounds in dogs, however did show a difference from the untreated wounds (Fig. 11). In 2 instances the control wound was stronger than the extract treated wound, while in 8 instances the reverse was true. When one performs a statistical analysis of these figures one finds that this figure (8 out of 10) cannot be regarded as very significant. The same conclusion is arrived at by the use of the coefficient of variation to calculate the expected variation by pairs and compare those with the differences actually observed. There is about one chance in twenty five of differences equal or greater than the observed arising. We may conclude that the experiments in the case of the dog wounds suggest that the application of splenic extract promotes wound healing as measured by the tensile strength of the wounds, but further work is required to prove that fact.

Fig. 10. Tensile strength of skin wounds in dogs, treated with splenic extract. — wounds treated with splenic extract, o—o, control wounds oo, individual wound strengths.

ANALYSIS OF STUDY

There is little indication for generalizations on experiments such as the foregoing for they have to be evaluated on their face value and it is also to be remembered that they are on animals and not on man. It is, however of interest to point out again the important factor of variation in healing in individual animals, and in animals with multiple wounds. This is knowledge that is of paramount importance in any study of wound healing. The factor of variation should hold true for open wounds as well as for incised wounds.

The gain in tensile strength of secondarily closed wounds coincides with the clinical experience of many (4) that disrupted wounds heal remarkably well if the patient survives. The fact that the contaminated wounds did well and the organisms disappeared rapidly is not salve for the surgeon's conscience but merely another indication of nature's ability to protect.

Catgut versus silk has long been a subject of dispute between the advocates of each. Here silk was shown to be superior to catgut as a skin suture in guinea pigs. The actual tensile strength of the suture material did not enter as the sutures were removed before the wounds were tested. The reaction of the tissues to cat

gut, which has been demonstrated by others (3) to be greater than that to silk, must be the underlying cause for the superiority of silk. This reaction, which is an exudative one, presumably delayed the onset of fibroplasia in these wounds.

The question of substances that may accelerate the healing of wounds is of perennial interest to the surgeon. The embryonic extract epicutan produced negative results as judged by the tensile strengths of the wounds concerned, but the trial of splenic extract in dogs was very suggestive of a beneficial action upon wound healing. This was not true in guinea pigs. Whether it is wise to attempt to accelerate the healing of incised wounds is a debatable point. In view of the variation in the healing of wounds in animals, an unstable factor in each individual, which is the inherent ability to repair damaged tissue, is more important than substances which accelerate wound healing when applied locally. This does not intend to imply that local treatment of wounds is not essential, but means that nature should be helped but not pushed. This conception is based upon observations on incised wounds, and it would not be wise to apply it to open surface wounds. Additional work on this subject will be necessary in order to clarify the problem.

SUMMARY

- 1 A method for testing the tensile strength of wounds in animals *in vivo* is reported.
- 2 Normal curves of wound healing, as measured by the wound tensile strength of skin wounds *in vivo* in guinea pigs and dogs, are demonstrated.

3 The variation of the ability to heal among single animals and in the individual animal with multiple wounds is shown.

4 Experiments showing the value of secondary suture are described.

5 The superiority of silk over catgut as a skin suture is demonstrated.

6 Embryonic extract epicutan was found to have no effect, good or bad, upon wound healing as measured by wound tensile strength in dogs.

7 Splenic extract was found to be of questionable benefit in the acceleration of wound healing as measured by wound tensile strength in dogs.

I wish to record my thanks to Professor J. R. Learmonth for his advice and guidance in carrying out this work, and to acknowledge my indebtedness to the technical staff of the Wilkie Surgical Research Laboratory for their help. I also am indebted to Dr. W. O. Kermack of the Royal College of Physicians' Laboratory, Edinburgh, for his aid in the statistical analysis.

MALIGNANT LESIONS OF THE CECUM AND ASCENDING COLON

CHARLES W. MAYO, M.D. F.A.C.S. and W. RANDOLPH LOVELACE, II, M.D.
Rochester, Minnesota

RESECTION of the right half of the colon including the cecum is the surgical procedure of choice in a variety of pathological conditions which affect this particular segment of the intestine. The most common of these is a malignant lesion.

The basis for this study is a series of 885 cases of malignant lesions of the cecum and ascending colon in which operation was performed at the Mayo Clinic in the years 1907 to 1938 inclusive.¹ These constitute about 80 per cent of all the malignant lesions of the cecum and ascending colon seen in this period. Cases in which the lesion was situated in the hepatic flexure of the colon were included but not those in which the lesion was distal to the hepatic flexure. In 358 or 40 per cent, of the cases the lesion was situated in the cecum and in 527 or 60 per cent it was situated in the ascending colon including the hepatic flexure.

In 295 of the 885 cases or 33 per cent, the operative procedures performed were not curative in purpose they included, for instance, exploration and biopsy, palliative ileocolostomy, cecostomy, and ileostomy. Also included in this group are a few cases in which palliative resection was performed in the presence of extensive metastatic involvement of the lymph nodes or liver.

In 590 or 67 per cent, of the 885 cases, resection was performed with a view to cure. This is worthy of note because nonpalliative resection is attempted in only about 50 per cent of cases of malignant lesions of the left half of the colon in which surgical treatment is employed. In 247 of the 590 cases the lesion was situated in the cecum and in 343 cases it was in the ascending colon.

From the Division of Surgery, the Mayo Clinic. Read before the meeting of the Western Surgical Association, Los Angeles, California, December 3 and 16, 1939.

¹The statistical calculations included in this study were made under the auspices of the Division of Biometry and Medical Statistics of the Mayo Clinic.

The percentage of surgical cases of malignant lesions of the cecum and ascending colon in which nonpalliative resection could be attempted has remained rather constant in the 32 years covered by this study although in the past 5 years there has been about a 3 per cent increase in the cases in which this was possible. This may be accounted for not only by earlier diagnoses but also by improvements in auxiliary surgical technique.

In order to determine the relative frequency of malignant lesions of the cecum and ascending colon and of other segments of the large intestine, we studied the histories of all cases in which operation for malignant lesions of the large intestine, including the anal canal, was performed at the clinic in the years 1907 to 1938, inclusive. The cases in which the lesion involved the cecum or ascending colon comprised 30 per cent of the cases in which the involvement was proximal to the termination of the sigmoid and 12 per cent of the entire group of cases.

This review is based on the summation of the operative experience of a rather large group of different surgeons. However the group was thought to be sufficiently homogeneous to permit us to make a detailed statistical study of certain aspects of the problem.

AGE AND SEX

In this series of cases the age incidence was somewhat similar to that of carcinoma situated elsewhere in the body (Table I). In 20, or 2.3 per cent, of the 885 cases the patients were less than 30 years of age. In 14 of the 20 cases the lesion was in the cecum.

The impression of the surgeon that carcinoma which affects young people is more malignant than that which affects old people was supported by the results of a calculation of the 5 year survival rate. For the patients less than 40 years, the 5 year survival rate was

54 per cent and for the older patients it was 58 per cent. Deaths from all causes are included for these calculations. Since older people have a general death rate higher than younger people, correction should be made for the higher rates of the older people from other causes than cancer, if the true contrast so far as cancer is concerned is to be seen. When these survival rates were corrected for the normal death rates from causes other than cancer in the respective age groups, the 5 year survival rate for patients less than 40 years, exclusive of deaths from other causes than cancer, was found to be 55 per cent, and that for the patients 40 years or more of age was 66 per cent. This indicates a greater virulence of malignancy among the younger group.

RELATION OF MORTALITY RATE TO THE SURGICAL PROCEDURE

The gross hospital mortality rate for the entire series of 885 cases was 23.5 per cent. These cases include those in which only a palliative procedure was carried out as well as those in which it was possible to carry out resection with the object of cure. All deaths in the hospital are included, regardless of the cause of death or the time that had elapsed since operation.

In general, which is safer, a one stage or a two stage resection of the cecum and ascending colon? Most surgeons consider a two stage operation the safer procedure from the standpoint of operative mortality, and statistics from various hospitals and clinics seem to bear this out. Ransom recently reported a mortality rate of 32 per cent for one stage resection, in contrast to a mortality rate of 20 per cent for two stage operations. Allen (1, 2) reported a mortality rate of 20.5 per cent for one stage resection in 73 cases of carcinoma of the right portion of the colon and a mortality of 11 per cent in 18 cases in which a two stage procedure was performed.

Pemberton and Whittaker reported a series of 46 consecutive cases, in 8 of which single stage procedures were performed and in 38 of which two stage procedures were performed. In addition to the 46 cases, there were also 5 cases in which ileocolostomy was performed as the first part of a two stage operation. In the

TABLE I — AGE AND SEX OF PATIENTS TREATED SURGICALLY DURING 1907 TO 1938, INCLUSIVE

Age years	Lesion in cecum		Lesions in ascending colon	
	Patients	Per cent	Patients	Per cent
0-9	1	0.3	0	
10-19	5	1.4	0	
20-29	8	2.2	6	1.1
30-39	33	9.2	54	10.2
40-49	69	19.3	101	19.2
50-59	117	32.7	151	28.7
60-69	99	27.7	173	32.8
70+	26	7.3	42	8.0
Total	358	100	527	100
Youngest patient	6 years		23 years	
Oldest patient	79 years		84 years	
Mean age	53.7 yrs		55.2 yrs	
Males	218	60.9	330	62.6
Females	140	39.1	197	37.4

38 cases in which the two stage resection was performed there were 2 deaths, a mortality rate of 5.2 per cent, there were 2 deaths in the 5 cases in which ileocolostomy only was performed as the first of a two stage procedure. In the total group of 43 cases in which two stage resection was contemplated, the mortality was 9.3 per cent. In the 8 cases in which a single stage operation was performed, there was 1 death. With good reason, Pemberton is an advocate of the two stage method of resection of the right half of the colon.

Harvey, however, advocated the one stage procedure and, in 1934, reported 18 cases of carcinoma of the cecum in which operation was performed with a mortality of 11 per cent. Stone and McLanahan (1939) advocated a one stage procedure whenever possible and also an aseptic type of end-to-end anastomosis. Jones advocated the use of an end-to-side anastomosis when a one stage resection is carried out. Lahey advocated a modified Mikulicz procedure with staggering of the proximal portion of the ileum for removal of malignant lesions in the right portion of the colon. He said that this type of operation obviated the danger of leakage and peritoneal contamination.

MALIGNANT LESIONS OF THE CECUM AND ASCENDING COLON

CHARLES W. MAYO, M.D., F.A.C.S., and W. RANDOLPH LOVELACE, II, M.D.
Rochester, Minnesota

RESECTION of the right half of the colon, including the cecum, is the surgical procedure of choice in a variety of pathological conditions which affect this particular segment of the intestine. The most common of these is a malignant lesion.

The basis for this study is a series of 885 cases of malignant lesions of the cecum and ascending colon in which operation was performed at the Mayo Clinic in the years 1907 to 1938 inclusive.¹ These constitute about 80 per cent of all the malignant lesions of the cecum and ascending colon seen in this period. Cases in which the lesion was situated in the hepatic flexure of the colon were included but not those in which the lesion was distal to the hepatic flexure. In 358 or 40 per cent, of the cases the lesion was situated in the cecum and in 527 or 60 per cent it was situated in the ascending colon, including the hepatic flexure.

In 295 of the 885 cases, or 33 per cent, the operative procedures performed were not curative in purpose; they included, for instance, exploration and biopsy, palliative ileocolostomy, cecostomy and ileostomy. Also included in this group are a few cases in which palliative resection was performed in the presence of extensive metastatic involvement of the lymph nodes or liver.

In 590 or 67 per cent, of the 885 cases, resection was performed with a view to cure. This is worthy of note because nonpalliative resection is attempted in only about 50 per cent of cases of malignant lesions of the left half of the colon in which surgical treatment is employed. In 247 of the 590 cases the lesion was situated in the cecum and in 343 cases it was in the ascending colon.

From the Division of Surgery, the Mayo Clinic.
Read before the meeting of the Western Surgical Association, Los Angeles, California, December 3 and 4, 1939.
¹The statistical calculations included in this study were made under the auspices of the Division of Biometry and Medical Statistics of the Mayo Clinic.

The percentage of surgical cases of malignant lesions of the cecum and ascending colon in which nonpalliative resection could be attempted has remained rather constant in the 32 years covered by this study, although in the past 5 years there has been about a 3 per cent increase in the cases in which this was possible. This may be accounted for not only by earlier diagnosis but also by improvements in auxiliary surgical technique.

In order to determine the relative frequency of malignant lesions of the cecum and ascending colon and of other segments of the large intestine, we studied the histories of all cases in which operation for malignant lesions of the large intestine, including the anal canal, was performed at the clinic in the years 1907 to 1938 inclusive. The cases in which the lesion involved the cecum or ascending colon comprised 30 per cent of the cases in which the involvement was proximal to the termination of the sigmoid and 12 per cent of the entire group of cases.

This review is based on the summation of the operative experience of a rather large group of different surgeons. However the group was thought to be sufficiently homogeneous to permit us to make a detailed statistical study of certain aspects of the problem.

AGE AND SEX

In this series of cases the age incidence was somewhat similar to that of carcinoma situated elsewhere in the body (Table I). In 20 or 2.3 per cent, of the 885 cases the patients were less than 30 years of age; in 14 of the 20 cases the lesion was in the cecum.

The impression of the surgeon that carcinoma which affects young people is more malignant than that which affects old people was supported by the results of a calculation of the 5 year survival rate. For the patients less than 40 years, the 5 year survival rate was

54 per cent and for the older patients it was 58 per cent. Deaths from all causes are included for these calculations. Since older people have a general death rate higher than younger people, correction should be made for the higher rates of the older people from other causes than cancer, if the true contrast so far as cancer is concerned is to be seen. When these survival rates were corrected for the normal death rates from causes other than cancer in the respective age groups, the 5 year survival rate for patients less than 40 years, exclusive of deaths from other causes than cancer, was found to be 55 per cent, and that for the patients 40 years or more of age was 66 per cent. This indicates a greater virulence of malignancy among the younger group.

RELATION OF MORTALITY RATE TO THE SURGICAL PROCEDURE

The gross hospital mortality rate for the entire series of 885 cases was 23.5 per cent. These cases include those in which only a palliative procedure was carried out as well as those in which it was possible to carry out resection with the object of cure. All deaths in the hospital are included, regardless of the cause of death or the time that had elapsed since operation.

In general, which is safer, a one stage or a two stage resection of the cecum and ascending colon? Most surgeons consider a two stage operation the safer procedure from the standpoint of operative mortality, and statistics from various hospitals and clinics seem to bear this out. Ransom recently reported a mortality rate of 32 per cent for one stage resection, in contrast to a mortality rate of 20 per cent for two stage operations. Allen (1, 2) reported a mortality rate of 20.5 per cent for one stage resection in 73 cases of carcinoma of the right portion of the colon and a mortality of 11 per cent in 18 cases in which a two stage procedure was performed.

Pemberton and Whittaker reported a series of 46 consecutive cases, in 8 of which single stage procedures were performed and in 38 of which two stage procedures were performed. In addition to the 46 cases, there were also 5 cases in which ileocolostomy was performed as the first part of a two stage operation. In the

TABLE I — AGE AND SEX OF PATIENTS TREATED SURGICALLY DURING 1907 TO 1938, INCLUSIVE

Age years	Lesion in cecum		Lesions in ascending colon	
	Patients	Per cent	Patients	Per cent
0-9	1	0.3	0	
10-19	5	1.4	0	
20-29	8	2.2	6	1.1
30-39	33	9.2	54	10.2
40-49	69	19.3	101	19.2
50-59	117	32.7	151	28.7
60-69	99	27.7	173	32.8
70+	26	7.3	42	8.0
Total	358	100	527	100
Youngest patient	6 years		23 years	
Oldest patient	79 years		84 years	
Mean age	53.7 yrs		55.2 yrs	
Males	218	60.9	330	62.6
Females	140	39.1	197	37.4

38 cases in which the two stage resection was performed there were 2 deaths, a mortality rate of 5.2 per cent, there were 2 deaths in the 5 cases in which ileocolostomy only was performed as the first of a two stage procedure. In the total group of 43 cases in which two stage resection was contemplated, the mortality was 9.3 per cent. In the 8 cases in which a single stage operation was performed, there was 1 death. With good reason, Pemberton is an advocate of the two stage method of resection of the right half of the colon.

Harvey, however, advocated the one stage procedure and, in 1934, reported 18 cases of carcinoma of the cecum in which operation was performed with a mortality of 11 per cent. Stone and McLanahan (1939) advocated a one stage procedure whenever possible and also an aseptic type of end-to-end anastomosis. Jones advocated the use of an end-to-side anastomosis when a one stage resection is carried out. Lahey advocated a modified Mikulicz procedure with staggering of the proximal portion of the ileum for removal of malignant lesions in the right portion of the colon. He said that this type of operation obviated the danger of leakage and peritoneal contamination.

One of the most important advantages of one stage as compared to the two stage resection of the colon in cases of neoplasm in our opinion concerns the factor of time. It is reasonable to suppose that the longer a malignant lesion remains in the body the greater is the risk of extensive metastasis which will preclude resection.

One of us (C. W. M.) has performed one stage resection of the right portion of the colon in an all inclusive series of 49 cases up to and including 1939, with a hospital mortality rate figured regardless of time or cause of 12.2 per cent. In the same period of time, a two stage resection was performed in 8 cases in this group 1 death occurred after completion of the second stage of the operation and 2 deaths occurred following an ileotransverse colostomy. In fairness to the two stage resection however it must be stated that in the cases selected for this type of operation the condition was more serious, an important point to be kept in mind.

Until the present report, no large series of cases of malignant lesions of the cecum and ascending colon has been presented for comparison as to operative procedures and results. Of course, a review of such a large series as is included in the present report is made possible only by including the experience of several surgeons who have differed among themselves as to the advantages of different types of operations. It does not take into account the advantages of improved pre-operative and post operative care characteristic of recent years. In the 590 cases in which operations were carried out with a view to cure, there were 315 in which a one stage resection was performed, 246 in which a two stage procedure was utilized and 29 in which more than a two stage procedure was employed. A review of the hospital mortality for this entire group would seem to indicate that the one stage resection has an advantage over the two stage procedure as the one stage resection resulted in a hospital mortality of 22.2 per cent as compared with a hospital mortality rate of 28.9 per cent for the two stage procedure 15 per cent after the first stage and 23.9 per cent after the second stage. In the group of 29 cases in which resection was performed in

more than two stages, there were 10 deaths in the hospital.

No case in which death has occurred in the hospital has been eliminated regardless of how long after the operation it occurred or the cause of death. There is no intention in presenting the general mortality figures to depreciate any individual's surgical method because it is evident that the individual surgeon may master a method and obtain results which will justify the method in spite of what may appear to be a condemnation in the general picture.

In considering the hospital mortality rate for one stage operations from the viewpoint of type of anastomosis, it was found that the hospital mortality rate was 22.7 per cent in cases in which a side to-side anastomosis was done, 23.4 per cent in cases in which an end to-side anastomosis was performed, and 19.2 per cent in cases in which an end to-end anastomosis was done. Because of the technical difficulties, it is often impossible to carry out an end to-end anastomosis, but it apparently is the procedure of choice when it can be accomplished. Comparison of the 5 year survival rates for the one stage and two stage types of resection showed a small advantage in favor of the one stage type after 5 years even with the hospital mortality disregarded. The 5 year survival rate in cases in which the one stage procedure was used was 57.8 per cent as compared with 55.3 per cent for the two stage. Although the difference is small and must be viewed as tentative until an even larger series of cases can establish the survival rates, it is interesting that in this total series of cases the one stage operation is advantageous both so far as the immediate hospital mortality is concerned and also so far as the 5 year survival of those who withstood the operation successfully is concerned.

A review of the hospital mortality according to the age of the patient confirmed the general impression that mortality is very definitely greater as the age of the patient increases. While the hospital mortality for the whole group of patients who were subjected to operation with a view to cure was 25.6 per cent, that for the individuals less than 40 years of age was only 14.7 per cent, that for

individuals between 40 and 60 years was 21.0 per cent, while the mortality rate for individuals more than 60 years of age was above the average rate and increasingly so for individuals more than 70 years of age. In cases in which the value for the hemoglobin was less than 7 grams per 100 cubic centimeters of blood the mortality rate was 36.8 per cent, in cases in which the value was between 7 and 12 grams the mortality rate was 28.1 per cent, and in cases in which the value was more than 12 grams the rate was 22.3 per cent. Similarly, in cases in which the erythrocyte count was less than 3.5 million per cubic millimeter of blood the mortality rate was 39.5 per cent, as contrasted with a mortality of 16.7 per cent in cases in which the erythrocyte count was more than 4.5 million. In 97 patients in whom there was a perforating lesion, the mortality rate was 29.9 per cent, this as contrasted with a mortality rate of 24.7 per cent in those patients in whom perforation had not taken place.

MORBIDITY ASSOCIATED WITH ONE STAGE AND TWO STAGE RESECTION

In cases in which a one stage operation was performed 49 per cent of the patients spent a total time of less than 20 days in the hospital and 43 per cent spent between 20 and 35 days, the average was 21 days. In cases in which a two stage resection was performed, 22 per cent spent a total of between 20 and 35 days in the hospital and the rest spent more than 35 days in the hospital, the average was 45 days. Only 8 per cent of patients subjected to a one stage resection were in the hospital more than 35 days, 78 per cent of those who underwent a two stage procedure spent this length of time in the hospital. In addition, one must also consider the fact that in more than half of the cases in which the two stage procedure is used the patients must spend time, sometimes a considerable period, in the hospital between the first and second stages of the operative procedure. In the cases in which a two stage resection was performed, 13 per cent of the patients were out of the hospital for 20 to 34 days between the stages and 13 per cent were out of the hospital for 35 days or more.

THE QUESTION OF ILEOSTOMY

It often has been stated that an ileac stoma made proximal to the site of anastomosis acts as a safety valve which prevents distention of the intestine with gas and fluid and thus tends to prevent leakage and subsequent peritonitis. Our study indicates that ileostomy is an added hazard which increases the operative mortality. Ileostomy was performed in 98 cases. In all of these cases the Witzel method was used. The mortality rate in the 98 cases was 6 per cent higher than it was in the cases in which enterostomy was not performed. Ransom found that the increase in the mortality rate in cases in which ileostomy is performed usually is due to general peritonitis or severe infection at the site of the incision, which often results in a persistent fecal fistula. He concluded that performing an enterostomy is not only unnecessary but unwise. Our findings have led us to the same conclusion.

ONE STAGE RESECTION

In the majority of cases in which resection of the colon has been performed for malignant lesions of the cecum and ascending colon by one of us (C W M), a one stage procedure has been employed and an end-to-side ileo-transverse colostomy has been performed.

PROGNOSIS AND FURTHER STATISTICAL ANALYSIS

At present the most satisfactory method of determining prognosis in the individual case of malignant lesion of the colon, rectosigmoid, rectum, and anus is the combined application of Broders' method of grading of malignancy, which is based on the dedifferentiation of cells, and Dukes' (4, 5) classification of such neoplastic growth, which is based on the mural penetration of malignant cells.

Simpson and one of us (C W M), in 1939, reported on the effect of mural penetration of carcinoma cells in the colon. The work was based on an examination of 120 carcinomas of the colon. Dukes' (4, 5) method of classification was modified to fit growths situated above the rectosigmoid and at the same time the growths were classified according to Broders' method of grading. It was concluded that the deeper the carcinomatous penetration, the

TABLE II.—GRADE OF MALIGNANCY

Site of involvement	Cases*	Per cent of cases			
		Grade 1	Grade 2	Grade 3	Grade 4
Cecum	206	1.4	37.8	33	13.1
Ascending colon	277	9.4	34	47.8	9

*Only cases in which grade of malignancy was determined are included.

greater was the probability of involvement of lymph nodes and the greater was the probability that the growth would be of a histological grade of malignancy. Likewise, the higher the histological grade of malignancy the deeper is mural penetration likely to be found, and the more likely it is that lymph nodes will be involved. However these factors were found to operate independently to a certain degree in that for any class of penetration the prognosis is poorer the higher the histological grade of malignancy similarly for any histological grade of malignancy the deeper the penetration the worse the prognosis. The most precise prognosis is obtained if Dukes (4) method of classification of mural penetration is combined with Broders histological grading of malignancy.

Does the situation of the lesion have any influence on the grade of malignancy? If so what is the status of the cecum and right half of the colon in such a consideration? In both the cecum and the ascending colon one of the most typical features of malignant lesions is the high percentage of tumors which have a low grade of malignancy. While tumors which have a high grade of malignancy do occur and in a percentage greater than in the left portion of the colon, rectosigmoid, rectum, and anus, analysis of the cases in which Broders scheme of grading was used (Table II) shows that 65.6 per cent of the carcinomas in the cecum and 64.2 per cent of the tumors in the ascending colon were grade 1 or 2. Classification of these tumors by Dukes system would in all likelihood be of additional value, but an insufficient number of neoplasms in this present series of cases were classified by this method to warrant analysis.

Does the grade (according to Broders classification) have any influence on the percentage of cases in which metastatic involvement

TABLE III.—GRADE OF MALIGNANCY AND METASTASIS TO LYMPH NODES

Grade	Cases*	Cases with nodal metastasis	
		Number	Per cent

2	7		29
3	60		31.7
4	14	2	14.3

*Only cases in which grade of malignancy was determined are included.

of lymph nodes is present? Metastatic involvement of lymph nodes was noted in 28 per cent of the total number of cases in this series. It was present in 31 per cent of the cases in which the lesion involved the cecum and in 26 per cent of the cases in which the lesion involved the ascending colon. This percentage of metastasis is higher than it is for the rest of the large intestine. In those cases in which the grade of malignancy was determined histologically there was a progressive increase in the incidence of involvement of lymph nodes as one passes to the higher grades of malignancy (Table III). The lymph nodes were involved in only 22 per cent of the cases in which the lesion was grade 1 whereas they were involved in 59 per cent of the cases in which the lesions were grade 4. This brings out the correlation between the degree of malignancy as it is determined by histological examination and as it is manifested by metastatic involvement. Metastasis to the liver was noted by the surgeon in only 10 per cent of the cases.

It has been noted that when spread of a malignant growth begins through lymphatic channels, the nearest lymph nodes are usually the first to be involved. Neither such involvement of lymph nodes adjacent to the tumor nor even involvement of lymph nodes deep in the mesentery of the right colon should preclude resection of the malignant lesion.

In a recent review of the lymphatic distribution of the colon and rectum Looney stated that there are comparatively few lymph nodes along the ascending colon and those that are present lie along the medial margin. The lymphatic vessels of the appendix, cecum, ascending colon, hepatic flexure and the right

*Inquiry as of January 1, 1939. The 5 year group comprises the patients operated on 5 years or more prior to the time of inquiry, that is, 1933 or earlier; the 10 year group comprises those operated on in 1928 or earlier, and so forth.

two-thirds of the transverse colon follow, in general, the distribution of the superior mesenteric artery and end in the superior mesenteric lymph nodes whence the lymph passes through the gastro-intestinal trunk to the cisterna chyli. Raiford stated that the lymph supply to the cecum and right half of the colon is not abundant because this portion of the bowel is primarily concerned with the absorption of fluid. Despite these facts, it has been the observation of one of us (C. W. M.) that the lymph nodes of the right portion of the colon are efficient in maintaining within themselves metastatic deposits for a long period without permitting more distant spread.

SURVIVAL RATES

A word is in order about the way in which the calculation of survival rates was made. For each survival rate, the patients who were operated on the requisite number of years prior to the time of inquiry (which was as of January 1, 1939) were first selected. That is, for the 5 year survival rate the patients operated on in 1933 or earlier were selected, for the

Fig. 1. Survival rate in cases in which resection was performed with a view to cure.

10 year rate, those operated on in 1928 or earlier were selected and so forth. Obviously, therefore, the 5 year rate was calculated on the basis of a larger number of patients than the 10 year rate, the 10 year rate on a larger number of patients than the 15 year rate. Only the patients traced for the requisite number of years were included in the calculation. For instance, of the patients operated on 10 or more years before the date of inquiry, that is, in 1928, or earlier, only those who were traced for 10 or more years were utilized in the calculation of the survival rate. Hence, a patient who had been operated on 10 years prior to the time of inquiry but traced for only 6 years after operation and living at that time was included as traced for the 5 year calculation but was considered untraced for the 10 year calculation.

An exhaustive effort was made to trace all patients. When patients were delinquent in answering the routine follow-up letter, the local health departments, vital statistics bureaus, and so forth, were consulted to learn whether any record of death existed. In the end, only a small fraction of the patients remained untraced. More than 99 per cent of the patients who were operated on 5 years or more before this investigation were traced for 5 years or more.

The survival percentages were calculated on the basis of the patients who withstood the operation successfully, that is, operative mor-

TABLE V.—FIVE YEAR SURVIVAL RATES ACCORDING TO GRADE OF MALIGNANCY—OPERATION PERFORMED WITH VIEW TO CURE

3	51	51
4	66	4.8

tality was not included in the calculation of survival rates. Here, as elsewhere in this study operative mortality includes all deaths which occurred in the hospital regardless of cause of death or length of time in the hospital after operation.

Table IV presents the survival rates of the patients on whom resection was performed with the purpose of cure, and Figure 1 shows the survival curves for this group compared with that for the patients who underwent palliative operations and with that for the normal population. One of the most striking and encouraging results of this study is the finding of a survival rate exclusive of hospital mortality of 57 per cent at the end of 5 years for the group in which resection was performed. It is remarkable that 22 of the 88 patients, or 25 per cent, were alive at the end of 20 years. Further study of the 22 patients who survived 20 years or more shows that 10 patients have survived 25 years or more. On examination of the lesions of these patients 2 were not graded 2 were grade 1 3 were grade 2 2 were grade 3 and 1 was grade 4. In 1 case in which the lesion was grade 2 the patient is alive 31 years after resection, and in another case in which the grade of malignancy was not determined the patient is alive 30 years after resection.

Comparison of the 5 year survival rates and the site of involvement (Table IV) reveals that 53.6 per cent of the patients were alive at the end of 5 years in the group with lesions in the cecum in contrast to a survival rate of 59.5 per cent when the lesion was situated in the ascending colon. One might hazard the explanation that there is a tendency for the surgeon not to be radical enough in cases in which

*See footnote to Table IV

the neoplasm is limited to the cecum considering the fact, as has been shown, that in cases in which the lesion is in the cecum the incidence of metastatic involvement of the lymph nodes is higher than in cases in which the lesion involves the ascending colon.

A study of survival rates in relation to Broders histological method of grading of neoplasms confirms its prognostic value. The lower the grade of malignancy the greater are the relative number of patients alive at the end of 5 years. Table V shows how definite is the relationship between the grade of malignancy and the ultimate results. Of 31 traced patients with grade 1 lesions, 77.4 per cent were alive at the end of 5 years, whereas only 42.3 per cent of those whose tumor was grade 4 survived 5 years. It is clear that the grade of malignancy is an outstanding factor in determining results since the survival rate decreases progressively as one passes to the higher grades of malignancy.

The prognostic importance of involvement of the lymph nodes in addition to grade in respect to the 5 year survival rate is shown in Table VI. In cases in which involvement of the lymph nodes was associated with lesions which were grade 1 or 2 56.4 per cent of the traced patients were alive at the end of 5 years. In cases in which the grade of malignancy

nancy was the same but there was no involvement of the lymph nodes, 70.1 per cent of the traced patients were alive at the end of 5 years. Of the patients who had grade 3 or 4 lesions which were associated with involvement of the lymph nodes, 40.0 per cent of those who were traced survived for 5 years. In cases in which lesions grade 3 or 4 were not associated with involvement of the lymph nodes, 50.0 per cent of the patients who were traced were alive at the end of 5 years. Regardless of the grade of the malignant lesion, the chances are less in cases in which the lymph nodes are involved than they are in cases in which there is no involvement of the lymph nodes. This table also brings out that, given the fact of the presence or absence of involvement of lymph nodes, the higher the grade of the lesion, the lower will be the number of patients who are alive at the end of 5 years. It should also be noted that although the presence of involvement of the lymph nodes justifies a guarded prognosis, absence of this finding does not necessarily rule out regional extension or metastasis.

SUMMARY

This paper is based on a statistical study of 885 cases of malignant lesions of the cecum and ascending colon, including the hepatic flexure, in which surgical treatment was employed. The study is accumulative for the entire group of these cases which were seen at the Mayo Clinic in the years 1907 to 1938, inclusive. The results presented represent a summation of the work of a considerable number of different surgeons. It must be remembered, therefore, that this presentation is not based on the experience of an individual surgeon nor is it based only on the work as it is done today. For any particular type of operative procedure, whether it be performed in a single stage or in multiple stages, the individual statistics from the standpoint of mortality or morbidity may be better or worse than the general average disclosed by this study.

The main findings are as follows: malignant lesions of the cecum and ascending colon (including the hepatic flexure) constitute 30 per cent of malignant lesions of the abdominal colon, and 12 per cent of malignant lesions of

the entire colon including the rectosigmoid, rectum, and anal canal. In 62 per cent of the cases the patients were males and in 38 per cent they were females. In 80 per cent of cases in which the lesion involved the cecum or ascending colon the patients were between 40 and 70 years of age. The average age was 55 years. Anemia is not only an important diagnostic consideration but also definitely increases the operative risk.

Resection with a view to cure was performed in 67 per cent of the cases in this series. This percentage is higher than that reported in cases in which the lesion was found elsewhere in the large intestine. There are many varieties of single stage and multiple stage procedures employed in resection of the cecum and ascending colon. In the interest of the patient, the surgeon should be familiar with all of these procedures. The net hospital mortality rate in all cases and from all causes was 23.5 per cent. Mortality, on the same basis, in cases in which resection was performed with a view to cure, that is, excluding exploration and palliative operations was as follows: for one stage resection, 22.2 per cent, for two stage resection, 28.9 per cent, and for more than two stage resection, 34.5 per cent. This would seem to indicate that, when a one stage resection is found possible and surgically advisable, it has an advantage, in respect to average mortality, over other methods. In 8 per cent of the cases in which a one stage resection was performed, the patients remained in the hospital for more than 35 days, whereas in 78 per cent of the cases in which a two stage procedure was performed, the patients remained in the hospital for 35 days. In cases in which the two stage procedure was employed, 13 per cent of the patients were out of the hospital for 20 to 34 days and another 13 per cent were out for 35 or more days between the two stages. The duration of the malignant lesion in the body appears to have some influence on the 5 year survival rate. In the cases in which the patients were traced the 5 year survival rate was 2.5 per cent greater in cases in which a one stage resection was performed than it was in cases in which a two stage procedure was employed. Enterostomy as an auxiliary surgical measure in any method of

resection of the right portion of the colon appears to be contraindicated as a 6 per cent increase in mortality was found in cases in which this procedure was employed. Survival rates were calculated for various groups in the series. In the group of cases in which resection was performed with a view to cure the survival rate for 5 years was 57 per cent for 10 years, 48 per cent for 15 years, 37 per cent and for 20 years 25 per cent.

Grading of neoplasms by the method of Broders has again been shown to be of prognostic value. The survival rate decreases progressively with the higher grades of malignancy. In 65 per cent of the cases the lesion was grade 1 or 2. Involvement of the lymph nodes has been shown to increase directly with the grade of malignancy and to be of prognostic value both independently and in association with the grade of the neoplasm. In cases in which the lesion was grade 1 or 2 and not associated with involvement of the lymph nodes, the 5 year survival rate was 70 per cent. In cases in which the lesion was grade 3 or 4 and associated with lymphatic involvement the 5 year survival rate was 40 per cent. The presence of lymphatic involvement need not be regarded as presenting a hopeless prognosis. In cases in which the lymph nodes were involved 47.2 per cent of the patients were alive 5 years or more after resection.

Fig. Post-operative omental adhesions. Fixation of the omentum to low abdominal incision, left right lateral and dorsum and displacement, and fixation under tension of the transverse colon. Fixation under tension is more important in causing dysfunction of the colon than is displacement alone.

from standing erect. She got some relief from bearing down, and from applying heat to her abdomen. This pain was associated with nausea and regurgitation of food into her mouth after every meal. She began to have reflex vomiting of liquids and foods, about 3 months before the current admission. Constipation gradually increased during this whole period, until at the time of admission it had become intractable. Cathartics taken by mouth even in large quantities were of no avail, so that she came to lead an enema life. A large part of every morning was spent taking repeated enemas which entailed the greatest suffering because they irritated intense colics. Even with these repeated daily enemas she procured only one movement every 2 or 3 days. A bowel movement caused colic, but subsequently the defecation brought relief. As the constipation increased the colics became unbearable, and as the constipation became less severe the colics subsided somewhat. During the past 2 years this suffering was associated with unusual intermittent distention of the abdomen with borborygmi, which would develop rapidly and force her to let out her comet strings several inches. By this time she was so incapacitated and invalidated that she could not carry on her duties as nurse. Exertion caused great discomfort, and the effort of walking up and down stairs initiated intense colics. She learned from experience that by limiting the intake of nourishment to liquids during the cyclically recurring spells of

colic, distention, obstipation and nausea, she could bring about subsidence of an attack when nothing else would avail. As roentgen studies showed the transverse colon fixed and angulated in the pelvis, operation was advised and accepted. This revealed an omentum adherent in the pelvis and lower abdomen. When the adhesions were released, the medial 8 inch segment of the mobilized transverse colon was seen to form an acutely angulated loop with the two limbs of the angulated loop adherent to each other over a stretch of 4 inches, from constrictures in the gastrocolic omentum. These constrictures were severed, and the limbs of the transverse colon separated so as to eliminate the acute angulation. The omentum was resected, and the gastrocolic omentum was reefed. The entire small bowel was absolutely free of adhesions. Exploration of the rest of the abdomen was negative. Postoperative roentgen studies (Fig. 3 Case 3) showed the transverse colon elevated from the pelvis, reduced in diameter with more normal haustrations. All angulation had disappeared. There was marked axial shortening of the transverse colon, a spontaneous change apparently due to restoration of muscle tone in the released bowel. Following operation there was immediate restoration of spontaneous daily bowel movements for the first time in 2 years. On the tenth day the patient slipped from surveillance to try climbing stairs, and could do it without any discomfort. In 1 year she gained 5 pounds. For 3 years she has been completely free of all symptoms. There is no nausea, vomiting, or colic, and her bowels move daily with never any need for laxative or enema. The patient has been completely restored to normal health, and does a full day's work regularly.

In grouping the cases for study it is apparent that the initial symptoms appear from a few months to several years following an abdominal operation through a low abdominal incision. The syndrome was never encountered following operations through only a high abdominal incision. The symptoms group themselves into three types: first reflex symptoms, second, colon symptoms and third, pentoneal symptoms. The reflex symptoms, developing early or late in the picture, are characterized by epigastric distress after eating with nausea, regurgitation, and later vomiting. These reflex symptoms occur immediately while eating or within a half hour also with attacks of colic. They last from a few minutes, to half an hour or more. Vomiting in the later periods may assume such serious proportions that no liquids or foods are tolerated by the patient with resultant malnutrition, exhaustion and serious dehydration.

If the reflex disturbance is late in developing, the second group, or colon symptoms—colicky pain, intractable constipation, distention, pain with enemas, painful bowel movements with relief after defecation—appear and dominate the picture. The colon distress consists of intermittent spells of sharp colicky pain, usually in the epigastrium, sometimes in the right or left hypochondrium or lower toward the pelvis. In the absence of extreme fixation of the colon, occasional mild discomfort as from crowding by gas, may announce the bowel involvement. The colicky pain tends to maintain a constant location in each patient, that point depending upon the type of involvement of the colon by adhesions. If there be true angulation of the bowel, as revealed by roentgen study, the colicky pain may be at that point. If the function of the colon is disturbed by tension exerting itself at either the hepatic or splenic flexures, the localization of pain coincides with the area of disturbed physiology—right or left hypochondrium—sometimes with radiation to the back. The location of the pain is predominantly epigastric and right upper quadrant. In the event of failure to procure complete relief by simple lysis of adhesions, the position of the pain may change, depending upon the anatomical relocation of the transverse colon. The onset of the colicky pain is related to eating, defecation, or use of an enema (gastrointestinal activity), also to exertion and abdominal trauma (peritoneal irritation). It comes on arising in the morning, later in the day, or during the night. As time passes it comes more frequently, several times a day, and its intensity augments. Coming in the morning it may be so intense that the patient is unable to move from the bed for half an hour or more, and is forced to lie doubled over, arms around the abdomen, bearing down for relief. There is considerable audible borborygmi during the spells. The patient frequently experiences pain on breathing while enduring these colics.

Constipation varies directly with the intensity of the colic. In the early periods there are less frequent bowel movements with a feeling of incomplete evacuation. As the pain becomes more acute and lasting, the constipa-

tion becomes intractable. Massive quantities of cathartics are taken with diminishing effectiveness, and the patient ultimately comes to lead an "enema life." Daily enemas sometimes procure a movement once or twice in several days. The use of an enema or a spontaneous bowel movement may precipitate sudden agonizing colic, although complete defecation subsequently brings relief. There is usually direct correlation between the intensity of the colic and the degree of constipation. As the constipation becomes more marked, the pain is intensified. As the constipation abates, the attacks of pain subside—but only to recur with aggravation of the constipation. In some cases the attacks last for several days, subside, and then recur at intervals of several weeks. In other cases there is constant suffering. In the later periods of severity, the reflex symptoms of nausea and vomiting are aggravated. Vomiting comes once to several times a day and finally occurs whenever liquid or food is taken by mouth. At the height of the crisis of colic and constipation, this constant vomiting produces an extreme loss of nourishment and body fluids. There results an excessive loss of weight with marked dehydration. Rarely is there ever vomiting of upper bowel contents (so called fecal vomiting). A large number of these cases noted that some relief from colic was obtained by going on liquid diet which eliminates the bulky fecal stream. This fact probably accounts for the confusing relief experienced on a liquid Sippy regimen. This fact often leads to the suspicion of an ulcer. One patient attained comfort by maintaining constant watery stools with large daily doses of epsom salts.

Distention is not experienced by all the patients, despite this unmanageable bowel function. The most critical stage of malnutrition, from the vomiting and constipation phases of the syndrome, may be reached without any distention. In most cases, however, distention occurs in varying degrees from intermittent increase of the girth by 2 or 3 inches, to the extreme sudden distention of an acute obstruction. Such an extreme distention is unusual, but may appear overnight. One patient awakened one morning with so marked a distention that a nurse remarked

the "looked nine months along" This distention responds temporarily to medical measures, but only to recur promptly. In mild cases it occurs chiefly after eating. In severe cases, after several days or weeks of distention with associated vomiting and complete obstipation the distention gradually abates, with progressive subsidence of the other symptoms. Recurring chronic colics then dominate the picture until the next acute seizure develops.

The third group of symptoms (peritoneal) are due to constant tension and intermittent traction on the colon via this fixed omentum, from the pull of physical effort. Some patients become conscious of an intra-abdominal pulling sensation. Colicky pains are stirred up in the colon by the traction that results from exertion. Some patients are caught suddenly with acute discomfort after starting to walk, so that they have to stop on the street and return home. Flexion and extension of the leg or bending the body sometimes initiates pain. One patient had the first sudden seizure of agonizing pain after the unusual exertion of playing twenty-seven holes of golf another experienced the onset of colic after a severe fall which produced a tearing sensation within the abdomen still a third patient spent three fourths of every day in bed to avoid the discomfort caused by the jouncing of an obese abdominal wall other patients had to give up driving a car because of suffering entailed by the frequent extension of the foot on the pedals a few patients were awakened from sleep at night by pain initiated from extension of a leg kept flexed to minimize their discomfort. Women stated that they had to give up scrubbing floors because of the intense colic resulting. Kneeling in church acted similarly. The support of a girdle sometimes relieves the downward traction on the omentum and reduces the discomfort. This peritoneal phase is probably augmented by a low grade inflammatory process and microscopic tears of the omentum, as evidenced by the round cell infiltration and hemorrhagic exudate seen in histological sections. Clinically this possibility is suggested by occasional fevers (99 to 102 degrees) and leucocytosis (6 cases 11,000 to 15,000).

On physical examination, downward traction of the abdominal wall by the palms of the hands placed over the incision sometimes evokes the characteristic pain. Abdominal tenderness is frequently elicited and is possibly related to a low grade epiploitis with regional irritation of the involved peritoneum.

When first seen by the physician these patients present one of three composite clinical pictures. First, and least common, there is an explosive onset of symptoms bearing the features of an acute abdominal emergency. The patient is taken suddenly with unendurable colicky pain, which causes him to cry aloud, and requires repeated injections of morphia for relief. Repetition of the colics, associated with unusual constipation and vomiting lasts for days. All symptoms gradually abate. This type of onset is associated with falls and with unusual exertion. The second group of patients complain characteristically of chronic colics. They give a jumbled story of nausea vomiting intermittent distention and constipation with persistently recurring colic, which, until carefully integrated makes a confusing clinical picture. Acute exacerbations of these chronic symptoms may occur after a fall. Presumably tearing of the fibers of the adherent omentum augments the malfunction of the transverse colon and the related symptoms. This fact may well account for many baffling seizures of acute upper abdominal pain seen in patients with previous laparotomies, after a serious fall. The third clinical picture characteristic of the advanced stages of the lesion is that of recurring spells of apparent subacute intestinal obstruction. Frequently recurring intense colics are associated with marked persistent distention, cessation of bowel movements, nausea, and vomiting. This vomiting usually consists in immediate expulsion of slightly altered fluids and foods shortly after they are ingested. Very rarely there is vomiting of small bowel contents (fecal vomiting) but this suggests concomitant involvement of the small bowel by adhesions. Such obstructive seizures last for several days to weeks, gradually abate, and then are followed by the second type of clinical picture—chronic colic with constipation and occasional vomiting. Roentgen studies reveal

no evident cause for the clinically apparent obstruction. Too frequent recurrence of these critical seizures brings the patient to a state of extreme malnutrition and exhaustion, with death threatened by starvation and dehydration. One patient was observed for 1 year until her death from vomiting, debility, and inanition (Fig. 27).

PATHOLOGY

The postoperative fixation of an omentum to a low abdominal incision is usually a harmless occurrence. In occasional cases however, an adherent omentum undergoes progressive fibrosis and shortening which produces deleterious results. Fibrosis is initiated at the point of fixation of the omentum and propagates itself in response to the stimulus of trauma, exertion or infection. This progressive fibrosis replaces the fat and gives a firm consistency to the adherent segment of the omentum. The shirring action of this fibrosis may shrink this segment to a quarter or a sixth the length of the nonadherent portion of the organ. The extent of involvement of the omentum and colon by adhesions occurs in four degrees: first, adherence of a small area of omentum to the scar, second, adherence of a wide area with definite slight downward displacement of the transverse colon, third, marked contraction of a large fixed segment, pulling the colon deeply into the lower abdomen so as to underly the incision, fourth, extensive surface involvement of the peritoneum with extension of the fibrosing process through the greater omentum up into the gastrocolic omentum, and associated with marked ptosis of the colon. The displacement of the colon is usually proportionate to the degree of involvement of the adherent omentum (Fig. 2).

Histopathological alterations parallel these gross modifications of the omentum. In contrast to the normal omentum (Fig. 3) with its homogeneous network of fat cells containing occasional small bundles of connective tissue, the early stages of this lesion reveal propagating fibrillar processes of connective tissue. These fibrils invade the fatty tissue (Fig. 4), insinuating themselves among the fat cells. The fat cells thus encroached upon become

Fig. 2 Mechanism of displacement. Diagrammatic representation of the anatomic relations of transverse colon to the greater omentum, in the layers of which it is incorporated. A tensile force, which depresses the greater omentum will simultaneously depress and immobilize the transverse colon. A fixed progressively fibrosing and contracting omentum will steadily depress the level of the transverse colon, thus subjecting it to increased tension displacement, and fixation.

compressed, reduced in diameter, and sometimes obliterated. Coalescence of these fibrils yields heavy strands of connective tissue which propagate themselves in direct continuity. From these heavy strands, distinct peaked projections of connective tissue spread directly between adjacent fat cells, engulfing, isolating, and obliterating them (Fig. 5). Rarely, the stimulus of repeated operative trauma causes complete replacement of all the fat by a homogeneous sheet of connective tissue (Fig. 6). Detailed histological study reveals an obliteration of fat lobules by proliferating fibroblasts, with engulfment of the irritating end-products of disintegrating fat by numerous giant cells (Fig. 7). Granulating tissue appeared in the partially obliterated lobules of fat ahead of the fibrosing process. Active fibroblasts pervaded all the tissue. Scattered areas of hemorrhage and leucocytic infiltration depicted the influence of trauma.

Fig. 3.

Fig. 6.

Fig. 3. Normal omentum, connective tissue bundle. The web-like appearance of sheet of fat cells constituting the normal omentum. At the left of the section note the single discrete bundle of connective tissue. To the right of this is a small zone of collagen or elastic-like fibrous material. Note the complete absence of invasive characteristics, there being no involvement of adjacent fat cells by extension of this connective tissue component into the normal fat tissue. To the right of the central point of the section are many small discrete accumulations of lymphocytes and polymorphonuclear leukocytes. $\times 30$.

Fig. 4. Fibrous connective tissue. Left portion of section is composed of heavy condensed fibrils of connective tissue which has engulfed many individual fat cells, obliterating them in the areas of heavy collagen deposit. From this heavy deposit fiber fibrils insinuate themselves to the right among the individual fat cells, gradually fading away between the normal fat cells in the right part of the section. Note the smaller compressed appearance of the fat cells in the central portion of the section. At the upper and lower borders of the section is evidence of hemorrhage, to which this process of organization may be related, and which indicates tears from physical exertion and falls. $\times 30$.

Fig. 4.

Fig. 5.

Fig. 7.

Fig. 5. Strands of connective tissue. Here γ strands of connective tissue are directly invading and obliterating the lobules of fat. From the edges of these strands peaked projections of connective tissue extend directly between adjacent fat cells. Discrete fat cells appear engulfed along the border of the strands. This is evidence of direct extension in continuity of this connective tissue strand, in dependence of propagation by fine fibrils as seen in the preceding section. $\times 30$.

Fig. 6. Sheet of connective tissue. Complete replacement of fat lobules by continuous sheet of connective tissue. In the upper portion of the section are three completely surrounded lobules, slowly undergoing disintegration from invasion and compression by the sheet of connective tissue. To the extreme right is seen the terminal stage of obliteration, its accumulation of giant cells. $\times 30$.

Fig. 7. Giant cell obliteration of fat lobule. High power study of fat lobule mentioned in the preceding section. Disintegrating fat establishes foreign body brilliant reaction, which calls forth this giant cell reaction. In the same area are large numbers of eosinophiles and young active fibroblasts, evidence of simultaneous destruction of fat, and up-building of connective tissue elements. $\times 5$.

This fibrotic shirring of the fixed omentum caused yielding and downward displacement of the incorporated portion of the transverse colon with its ultimate fixation. At exploration whereas the left transverse colon and

omentum hung freely in the upper abdomen the right transverse colon passed sharply downward across the abdomen toward the right lower quadrant. Here the colon was fixed, not directly itself but indirectly by fix

Fig 8 Case 1 Left, pre-operative, right, postoperative views Roentgenogram before operation showed dilatation, loss of haustrations, and single fixed loop of transverse colon, postoperative roentgenogram showed bowel with smaller lumen, normal haustra, and U shaped loop of colon Patient was a female, aged 26 years who had had an appendectomy at 14 years Immediately she had spells of colic requiring morphia Dejection occurred every 7 days Intermittent distention became the size of 9 months' pregnancy Vomiting occurred several times daily She was awakened at night by colics At operation fecal impaction was noted proximal to fixed loop The adherent omentum was released Complete relief of symptoms followed the operation and she since had daily bowel movements

ation of its overlying omentum It was "frozen" to the abdominal wall under the incision This carried the right segment of the transverse colon into close proximity to the cecum and ascending colon, to which it occasionally was directly adherent In 3 cases,

Fig 10 Case 3 Left, pre-operative, right, postoperative views Pre-operative roentgenogram disclosed active contractions, angulated hepatic flexure, colon depressed to cecum, postoperative view showed less active contractions, arching hepatic flexure, elevated transverse colon (spontaneous) Patient was a female, aged 29 years She had had an appendectomy with drainage at 17 Eleven years later onset of "dry heaves" on physical exertion, with frequent colics, severe retching and vomiting, defecation every 7 days, intermittent distention Scrubbing floors started colic At operation adherent omentum released hysterectomy for pelvic inflammation Immediate relief Bowels move daily

Fig 9 Case 2 Left, pre-operative, right, postoperative views The pre-operative roentgenogram showed a dilated, elongated transverse colon, with double angled loop The postoperative film showed smaller lumen, spontaneously shortened transverse colon, and single loop Patient was a female, aged 31 years, who had had a left adnexectomy at 22 After 8 months she had spells of colic, distention, and vomiting Intense pains were induced with enemas or movements She had an 11 weeks' spell of extreme distention, persistent vomiting, and obstipation Walking or stretching leg caused colic She lost 60 pounds At operation the adherent omentum was released and upfolded Spasm of bowel was visible Result 75 per cent improved although there was some persistent vomiting but no colic or distention Bowels were regular She gained 15 pounds

15 per cent, the displacement of the colon was to the left

Additional direct observations of distortion and dysfunction of the transverse colon were made at the operating table In 3 cases taut

Fig 11 Case 4 Left, pre operative, right, postoperative The pre-operative roentgenogram showed a dilatation, diminished haustra, colon depressed in pelvis, curved left segment The postoperative film showed a reduced lumen, more normal haustra, colon elevated (spontaneously), angled left segment Patient was a female, aged 19 years Appendectomy was performed when she was 16 She had immediate right lower abdominal colics Eating or rising from bed doubled her over with pain She stopped eating much because of pain She was not constipated (1 of 2 cases) but occasional diarrhea At operation the adherent omentum was released and upfolded She was relieved of all symptoms and the bowels became regular

Fig. 3 Case 5. Left, pre-operative; right, postoperative films. The pre-operative film showed an elongated, dilated colon fixed in the pelvis with sharp angulation. The post-operative film showed spontaneously shortened colon with smaller lumen, elevated from pelvis and with no angulation. This case is reported here in detail. This is one of few instances in which the gastrocolic omentum as reeved. She had complete relief of all symptoms.

bands of fibrosed omentum passed from the involved segment of the transverse colon to the low incision under sufficient tension to angulate it. In 2 of these the proximal segment of colon was grossly distended with gas, and the distal segment was collapsed. In the third case there was a large obstructing fecal impaction proximal to the angulating band. Another case showed an extreme, abnormal looping of the colon with fixation of the loop to ascending colon. Another revealed a gross

Fig. 4 Case 6. Left, pre-operative; right, postoperative films. In the pre-operative film is seen an oblique line to transverse colon, from hepatic flexure to left lower abdomen, colon is elongated and splenic flexure is lower than hepatic. In the postoperative film is shown horizontal passage (spontaneous shift) of transverse colon from hepatic to splenic flexure, shortened colon (spontaneous), splenic flexure now the higher. Patient, a female, aged 34 years, who had had an appendectomy at 3. She had mild symptoms of cramping from gas, distention, constipation. Enemas caused intense colics. At operation small tongue of fixed omentum was found to displace the colon, but not to fix it firmly. This accounted for the mild symptoms. Operation gave relief. She also had hysterectomy for small fibroids.

angulation in the middle of transverse colon where the adhesions pulled it deeply into the pelvis. Two showed transient, firm localized spasm in mobilized segment of transverse colon after operative release of the adhesions, a condition foreign to the normal colon.

Fig. 4 Case 7. Left, pre-operative; right, postoperative films. The pre-operative view shows flattened transverse colon, distortion of the hepatic flexure, and extremely hyperperistaltic. The postoperative view shows curved looping colon arching hepatic flexure around haustra. Patient was female aged 35 years. Appendectomy as done when she was 3. She as admitted with diagnosis of bowel tumor. One year after first operation she suffered sharp colics and constipation. She had bimonthly spells of colic, bloating, obstruction, vomiting, and was confined to bed. Walking caused colic. Operation consisting of release and resection of adherent omentum gave complete relief of symptoms and bowels moved daily.

Fig. 5 Left, Case 8; right, Case 9. Physiologic evidence of obstruction—dilatation of bowel elongation, diminished haustrations. In Case 8 there was a likely dilated lumen of bowel, coincident with obstruction-like episode. There was an apparent functional disturbance of similar nature in all segments of the bowel. Roentgen report said it suggested obstruction but it was called "toilet." Case 9 there was extreme dilatation of all portions of colon, particularly of transverse colon, with complete disappearance of haustrations. This roentgenogram taken during an obstruction-like episode, had roentgen report of obstruction of unknown origin, because the lumen of the bowel was patent.

Fig 16 Physiologic evidence, No 2—hyperperistalsis—Case 7, No 3—segmental spasm—Case 14. In Case 7, left, we note excessive contractures of the colon with appearance of an abnormal number of deep haustrations. The overactive state is most apparent in the transverse colon although the appearance of hyperactivity carries over into the other segments. The descending colon is spastic. In Case 14, right, we note spasm in entire segment of descending colon, unaccompanied by any evidence of hyperactivity in other segments of the colon. The overspread of dysfunction into other portions of the colon than the transverse colon is suggested by this study. Spasm disappeared after surgical release of omental adhesions, and the clinical symptoms were relieved.

PATHOLOGICAL PHYSIOLOGY

Complete pre-operative and postoperative roentgen studies made in 20 of the cases yielded evidence of dysfunction of the colon in 14 of them, 70 per cent. Eight criteria of dysfunction noted may be grouped under two major subdivisions—the physiological and the anatomical evidences of dysfunction.

Fig 18 Physiologic evidence, No 4—focal spasm. Case 3. Left, pre-operative postero-anterior roentgenogram taken in horizontal position without traction, showing absence of spastic areas which appear in the film at right with traction. In 6 films taken before operation without traction and after operation with traction, there was always absence of spasm. Right, areas of spasm in transverse colon due to traction from omental adhesions when patient is put in Trendelenburg position. This may indicate the mechanism of production of pain upon exertion, whereby the fixed omentum pulls and irritates the bowel.

Fig 17 Physiologic evidence, No 4—focal spasm. In Case 22, left, we note spastic area at point of fixation of the right portion of the transverse colon by omental adhesions. This observation was made during an operation for another condition, and the roentgenogram was then taken after operation on a positively proved lesion. The roentgenogram at right, Case 2, was taken after an effort to expel the barium clysmas. This resulted in a drop of the unfixed left portion of the transverse colon into the lower abdomen, with persistent fixation of the elevated right portion. At the juncture of these two segments is a spastic area which also was visualized at the operating table, when the adherent bowel was released.

A. Physiological evidence. (1) Dilatation, diminished haustrations, and elongation of the transverse colon, sometimes interpreted as “colitis” and obstruction, were noted in 8 cases. (2) Hyperperistalsis occurred in 2 cases. (3) Segmental spasm was seen in 2. (4) Focal spasm occurred in 5. (5) Delayed emptying was evidenced in 5 cases by the markedly increased capacity of the colon to empty a

Fig 19 Case 6. Pre-operative, left, and, right, postoperative films showing physiologic evidence, No 5—delayed emptying, (a) barium enema. High grade retention of barium enema in the pre-operative roentgenogram, as compared with the efficient emptying seen in the postoperative roentgenogram, after lysis of omental adhesions. Note different placement, after operation, of transverse colon, which is a spontaneous shift following lysis of adhesions. There were only mild clinical symptoms in this case, even with marked displacement, because of the very limited fixation of the colon.

Fig. 30. Case 1. Pre-operative, left, and, right, post-operative films showing physiologic evidence. (a) 5—delayed emptying. (b) motor meal. Forty-eight hour retention of barium in right half of colon. This plate taken at 24 hours, duplicates exactly the fluoroscopic finding at 48 hours. Note excess gas in bowel. Quick emptying of motor meal following release of omental adhesions. Part of barium passed by rectum in 4 hours. This 24 hour plate shows nearly complete clearance of all barium from bowel. Not absence of gas.

clayms following release of the adhesions. 3 patients showed extreme delay in the transit of a barium meal from the cecum to the rectum up to 96 hours late retrograde transport of barium in the colon many hours after ingestion indicated that this delay may be due to reverse peristaltic waves.

B Anatomical evidence. Abnormal anatomical conditions were noted from which a consequent dysfunction may be fairly inferred. (6) Angulation, sufficient to impede emptying was noted twice. (7) Loop formation, of an extreme degree was observed once. (8) Fixation of the right transverse colon as noted under the fluoroscope in 8 cases. 40 per cent was verified by 3 methods. (a) pressure dis-

placement, by which compression and lateral displacement of the abdominal wall carried the fixed colon laterally with it. (b) segmental fixation by which the right transverse colon remained fixed while changes in position caused a shift in the position of the free left transverse colon. (c) traction displacement by which traction on the incision by adhesive strips fixed over the incision caused measurable shifts in the position of the fixed portion of the colon. Roentgen and operative observation never showed displacement of the stomach.

Correlation of these clinical and roentgen observations with known facts of gastrointestinal physiology convincingly establish this syndrome. The normal caudad transport of aliment is regulated as shown by Alvarez through gradients of activity in the bowel. There is a heightened intensity of rhythmicity tone and irritability in the upper bowel as contrasted with the lower bowel. This insures transport of chyme downward in the same way as the head of pressure at the spigot drives water through a hose to its nozzle. Also important in regulating gastro-intestinal activity is the gastrocolic (ileogastric) reflex described by Macewen (1904) and restudied by Hurst (1913). A neural interrelationship is established by this extrinsic nerve reflex between the stomach and the ileocecal region. By it the activities of these widely separated segments profoundly influence each other. i.e. the intake of food increases the rate of discharge of ileal contents into the colon and conversely irritability in the ileocecal region

Fig. 31. Case 3. Physiologic evidence. (a) 5—delayed emptying. (b) motor meal. Extreme delay in passage of barium through the colon due to dysfunction from omental adhesions. 48-hour retention of meal in cecum.

b, 48 hour progress, meal delayed in transverse colon. c, 7 hour progress, meal has reached descending colon. Note excess of gas in proximal colon. d, 60 hour at which time the meal has finally reached the rectum.

Fig 22 Physiologic evidence No 5—delayed emptying, (c) late retrograde transport (barium by mouth) Case 19 Left, at 48 hours three globules of barium have entered the distal left half of the transverse colon with part of the mass overlying, and part to the left of the spine Right, at 72 hours these same masses have been carried back towards to the right of the spine where they have been brought up against the angled portion of the fixed right portion of the transverse colon This case at 120 hours showed reflux of barium back into the cecum Note excess of gas

disturbs gastric motility, causing nausea and vomiting Disorders in the functioning of the tract arise from disturbances of these two factors First, a reversal of the gradients of activity by an irritant causes waves of reverse peristalsis which pass cephalad to the stomach and terminate in nausea and vomiting, second, abnormal stimulation of the gastrocolic reflex by an irritant in the ileocecal region produce

Fig 24 Anatomic evidence No 8—fixation of colon (a) pressure displacement Left, anteroposterior exposure showing fixed right loop of transverse colon close to mid line, and only slightly encroaching on the ascending colon Left half of transverse colon well over to the left overlying the descending colon No evidence of hyperperistalsis Right, postero-anterior position, showing marked displacement of right loop of transverse colon to outer border of ascending colon from pressure displacement, with the abdominal wall. Also left portion is drawn away from descending colon Hyperperistalsis, presumably from traction of the omentum, has appeared in the right portion of the transverse colon

Fig 23 Anatomic evidence No 6—angulation—Case 5, No 7—loop formation—Case 18 Left, Case 5 shows two arms of the transverse colon descending deeply into the pelvis so as to form an acutely angulated loop, fixed deeply in the pelvis At the operating table the two arms were adherent to each other with their apex showing such an abrupt turn as to create an obstructing angulation Right, Case 18 shows an excessively redundant loop of a tremendously dilated transverse colon The midportion of the transverse colon approximates the hepatic flexure and forms a loop down the full length of the ascending colon and up to the hepatic flexure The arms of the loop were adherent to each other and to the ascending colon by pathologic postoperative omental adhesions

irregularities in gastric function which are made manifest by nausea and vomiting—the most dramatic evidence of low bowel dysfunction

Integration of these clinical, roentgen, and physiological data explains the dysfunction

Fig 25 Anatomic evidence No 8—fixation of colon, (b) segmental fixation—Case 23 Left, supine position There is a normal curvature in the outline of the transverse colon This routine posteroanterior roentgenogram gives no suggestion of a fixation of the transverse colon Right, Trendelenburg position When the position is altered so that the head is down, the free left portion of the transverse colon is thrown into the upper abdomen At the same time the right portion is held fixed and angulated by omental adhesions Case 2 (physiologic evidence No 4) shows a similar fixation of the right half of the transverse colon when the left half dropped into the pelvis on evacuating the clymsa

Fig. 26. Anatomic evidence: N, 8—fixation of colon, () traction displacement. Left, traction upward on adhesions fixed over the incision. Hepatic flexure near the top of the second lumbar vertebra lateral to it. Loop of right transverse colon at level of the lower border of the fourth lumbar vertebra, on line with the iliac crests. Right, traction downward. By way of contrast hepatic flexure has dropped to the top of the third lumbar vertebra overlying it. The loop of right transverse colon is down to level of the lower portion of the fifth lumbar vertebra, far below the level of line across the iliac crests.

arising from omental adhesions. The irritating effect of omental adhesions on the colon has been noted clinically and by roentgen study. Clinically, the pull of the adhesions from exercise, stretching, extending the leg, driving an automobile, kneeling, washing the floor, walking, established a degree of irritability which announced itself locally by colic, and reflexly by nausea and vomiting, serious falls, producing a tearing sensation in the region of the adhesions, were followed by prolonged intense colics. Roentgenograms taken when traction was purposely produced on the colon via the omentum showed spasm which was not present in the absence of traction. 30 per cent of the pre-operative roentgenograms showed dilatation and diminished haustrations called colitis. 20 per cent showed a toneless elongation of the transverse colon which disappeared following release of the adhesions. Apparently from restored tone, 30 per cent showed heightened irritability as manifested by local or segmental spasm or general hyperperistalsis. 25 per cent showed evidence of delayed emptying of the colon. 15 per cent showed late retrograde transport of barium. Gross visual evidences of dysfunction noted at the operating table were excessive distention by gas of the segment of colon proximal to the adhesions, impaction of fecal matter proximal to the

Fig. 27. Case 20. a, In 1935, patient's weight 50 pounds. Hysterectomy years before in 1935. Perfectly ell., walking, no pain, bowels regular. b, In 1937 she weighed 75 pounds. For year spells of colic, vomiting, and progressive constipation, fits later without distention. Beginning obstruction-like episodes. c, In 1940, her weight 45 pounds. Repeated hospitalization for obstruction-like episodes, fits reflex vomiting. Total incapacity from colic, vomiting, constipation. Operated upon for omental adhesions. No other disease demonstrable after repeated roentgen studies and 3 laparotomies. Patient died in May, 1940, 4 years after onset of the syndrome, from inanition, exhaustion, and terminal pneumonia.

fixed angle of the bowel, transient marked spasm in the released segment of colon. From this demonstrated irritability in the colon arose the clinical manifestations of dysfunction—Intractable constipation, chronic colic, distention and borborygmi, reflex nausea and vomiting. This irritability was stimulated by normal functional activities, the intake of food and the act of arising from bed in the morning, stimulated a discharge of chyme from the ileum into the cecum which caused hyperactive irritability in the adherent bowel as manifested by intense colics and reflex vomiting, initiation of peristalsis by spontaneous bowel movement or injection of an enema, produced excruciating colic and sometimes vomiting. Thus so accurately do the clinical and roentgen observations integrate with the established facts of gastro-intestinal physiology as to justify presentation of this clinical picture as a specific syndrome having an adequate physiological background.

TREATMENT

Prevention of the lesion is of paramount importance. In operative procedures through low abdominal incisions, particularly in female patients in the early decades of life, all trauma to the omentum and peritoneal edges must be sedulously avoided, the omentum must never be caught in the suture line, a high lying omentum must never be pulled into the lower abdomen during the final peritoneal toilet, the peritoneum is best closed by a running mattress suture which produces ectropion of the rough edges, postural drainage by head blocks is preferable to Fowler's position, which crowds the omentum into the lower abdomen.

The surgical release of the omental adhesions is usually best accomplished through a low incision in close proximity to the adhesions. Occasionally, following multiple operations, or with roentgen evidence of ptosis of the colon requiring a reefing of the gastrocolic omentum, a high incision is preferable. Following release of the adhesions, three procedures proved valuable in preventing recurrence of the lesion, (1) resection of the released, fibrosed segment of omentum, (2) upfolding the omentum and fixing it with sutures to the gastrocolic omentum, (3) reefing the gastrocolic omentum, in the presence of marked ptosis, so as to elevate the bowel from the lower abdomen.

Further radical measures were attempted in 3 cases which suffered recurrence of incapacitating symptoms. Ileosigmoidostomy was first tried but it failed to bring relief because of a roentgen demonstrated reflux of barium back to the cecum past the adherent, irritable bowel. Right colic exclusion (transection of the transverse colon with stoma drainage of right half, left ileo-transverse-colostomy), thus isolating the irritable right colon from the functioning intestinal tract, was then tried. One patient showed no improvement, while 2 were improved about 50 per cent. These few cases do not permit evaluation of this method. Apparently there always will remain a small residuum of victims harboring vicious omental adhesions, to whom neither the internist nor the surgeon can bring lasting relief. During the postoperative period, in addition to routine postoperative care, elevation of the foot of the bed on blocks will carry the released

bowel into the upper abdomen away from the peritoneal tags from the released omentum. Amfetin was sometimes used.

ANALYSIS OF STUDY

The preponderant incidence of this disease among women is striking. Wherever noted, the sex of all cases reported in the literature was female. In this series, whereas 20 women, 85 per cent, were operated on, only 3 men, 15 per cent, were encountered. After excluding 6 pelvic operations, there was an etiological incidence of 14 appendectomy incisions among women as against 3 appendectomy incisions among the men. Except in terms of a constitutional sex factor, this extreme discrepancy between the sexes in the ratio of 4:1 is not easily explainable. Possibly the higher incidence of a ptotic habitus and low lying colon and omentum among women has some bearing on this anomaly.

Analysis of the age relationships is instructive. The primary operation which caused the adhesions was performed at an age under 20 years in 12 cases, during the twenties in 7 cases, during the thirties in 3 cases, after 50 years in 1 case, excluding the last case the average age at the time of the primary operation was 20 years, making the lesion a surgical hazard of youth. The time interval between the primary operation and the onset of symptoms ranged from a few months to 19 years, averaging $3\frac{1}{2}$ years. The duration of suffering between the onset of symptoms and the current lysis of adhesions ranged from 2 to 18 years, averaging 8 years. The current operation was performed at an average age of 33 years, the youngest patient being 17 years of age, and the oldest 67. Interval operations had been performed with no relief in 12 patients, 50 per cent of the group, with the sacrifice of many innocent organs, chiefly the gall bladder and pelvic organs, 5 patients had 1 interval operation, 2 had 2 operations, 2 had 3 operations, 2 had 4 operations, 1 had 6 operations—a grand tally of 29 unsuccessful interval operations.

The etiological significance of infection as compared with aseptic trauma, in causing these adhesions, does not appear as impressive in this series, as it did in the study by Muller

and Rademaker. In 16 of the present cases characterized by but one or two operations before the current lysis of adhesions, all hospital records were available for study. Analysis of the factors of operative trauma and infection grouped these cases naturally into 3 divisions. In the first subgroup there were 10 patients who were subjected to clean surgical procedures: there was no infection at the time of operation, the peritoneum was closed without drainage, the postoperative course was uneventful, with no unusual febrile reaction; the patients were discharged early, with cleanly healed incisions. Only the factor of aseptic trauma may be fairly incriminated in these cases. In the second group there were 3 cases in which operation was done for acute appendicitis. There was no recorded infection of the peritoneal cavity at the time of operation, and drainage was not instituted; the incision healed cleanly by first intention; the patients were discharged early. Although infection may have played a minor rôle in this group, certainly operative trauma appears to have been the major factor in causing these adhesions. The third group, presenting frank records of acute suppurative appendicitis with peritonitis, for which drainage was carried out, contained only 3 cases. Infection in this group was probably the dominant factor in causing adhesions. In summary, an evaluation of the factor of aseptic operative trauma versus infection as the causative agent of symptom-producing omental adhesions, indicates, that in 60 per cent of the cases, the adhesions resulted from aseptic operative trauma; that in 23 per cent they were due to aseptic trauma predominantly, with a minor element of infection; and that in only 17 per cent was the formation of adhesions due primarily to infection.

Diagnosis may be difficult if all the components of the syndrome are not present. In this series, the reflex symptoms, sometimes appearing late, were elicited from all but one patient; the elements of the colon complex were always present in part or entirely; peritoneal symptoms were noted in 13 instances, denied in 3 and not recorded in 7. In the present series a pre-operative diagnosis was achieved in 17 of the 23 cases, 74 per cent,

frequently by other physicians acquainted with this study. In differential diagnosis this lesion is widely disregarded. It is confused with gall bladder ulcer and pelvic diseases, and postoperative hernia. The most difficult differentiation is between omental adhesions and small bowel adhesions. The cyclical recurrence of obstruction-like episodes characterized by the early reflex vomiting of stomach ingesta, usually with spontaneous subsidence of the condition, is the chief distinguishing characteristic of omental adhesions. Effort¹¹ or "traction" colic, as well as the predominant "colon" features in the story, balance the differentiation more toward omental adhesions. "Focal vomiting instead of reflex vomiting almost commits the diagnosis to small bowel adhesions. Doubtlessly many clinical reports of satisfactory conservative management of intestinal obstruction include cases experiencing the cyclical exacerbation of symptoms from omental adhesions, unrecognized in the absence of surgical exploration; also it is quite possible that poor results following an apparently satisfactory technical management of small bowel adhesions may represent persisting symptoms from coexisting omental adhesions, not evaluated or corrected at the time of operation. The chief offense is labelling these sufferers psychoneurotics, as was done in 14 of the cases. Probably many functional diagnoses of atonic or spastic constipation, colitis, irritable colon, functional indigestion—all fortified by negative roentgen reports—represent inadequate evaluation of the secondary functional manifestations of omental adhesions.

The results of operative intervention—granting 25 per cent each for the four major complaints, such as colic, constipation, distention, and vomiting—show in the final summary of 20 completed cases: 12 patients, 60 per cent, completely relieved; 2 patients, 10 per cent, 75 per cent improved; 4 patients, 20 per cent, 50 per cent improved; 2 patients, 10 per cent, entirely unrelieved. One patient died from unexplained intestinal obstruction unrelieved by ileostomy. Another patient was followed for 4 years to the final outcome of death from recurring spells of vomiting, from debility and inanition. The surgical failures

among these "omental cripples" are a source of oppressing concern to the surgeon who must watch their hapless invalidism

CONCLUSION

A surgical experience with 23 cases of symptom producing omental adhesions, unrelieved by medical care, has yielded clinical, pathological, and roentgen data not previously published in the literature. These data appear to justify this presentation of a specific syndrome based on a dysfunction of the transverse colon, induced by pathologically fibrosed, adherent omenta, fixed under tension to a low abdominal incision.

I wish to express my indebtedness to Dr. Andrew E. O'Connell for his patience in carrying out repeated roentgen studies in this unpromising group of patients.

THE INTRA ABDOMINAL APPLICATION OF SULFANILAMIDE IN ACUTE APPENDICITIS

JAMES E. THOMPSON, M.D., F.A.C.S., JOHN A. BRABSON, M.D. and
JOHN M. WALKER, M.D. New York, New York

THIS paper is an analysis of acute appendicitis at the Roosevelt Hospital during the 6 year period of 1935 to 1940 inclusive the first 5 years represent an average background against which we hope to contrast the results of those cases during 1940 in which patients were treated by the intra-abdominal application of sulfanilamide.

Full credit must be given to the two men responsible for the first use of the drug at our hospital. First to Dr. R. Sterling Mueller who had the courage to sprinkle copious quantities into the peritoneal cavity in what seemed a hopeless case of peritonitis and second to Dr. William H. Casebaum, who leaning over his shoulder at the time of operation collaborated in the idea. The procedure was taken up immediately by one and then another of our surgical staff and now is routine when indicated.

To make a thorough analysis of this sort requires a great deal of careful, and frequently tedious, work tabulating facts garnered from histories for later interpretation. The histories of over 1000 cases during the 6 year period were reviewed in order to include only those cases of definitely acute appendicitis. We then eliminated several hundred borderline cases and others which were definitely not in this strict classification. Those thrown into the discard included cases of acute catarrhal intestinal, subsiding acute, chronic, and mechanical varieties cases of acute mesenteric lymphadenitis and frequent ones reported by the pathologist as showing either fibrosis or a normal appendix.

Our series thus represents, as accurately as it was possible to determine the distinct group of acute suppurative appendicitis known

From the Surgical Services of the Roosevelt Hospital, New York, N. Y.

Read before the Surgical Section of the New York Academy of Medicine, January 2, 1941

in operating room jargon as the 'red hot appendix.'

The surgical concept of the signs and symptoms, and the diagnosis of acute appendicitis has changed little in the past three decades but there have been great advances in the surgical technique. The mortality rate has continued to be sizeable in spite of these improvements, and periodically we are alarmed with reports that it is on the increase. In an effort to lower this rate, every encouragement should be and is given to any safe method which will accomplish this end.

The management of this condition at the Roosevelt Hospital has not changed since 1935 except in relationship to the use of sulfanilamide. We consider every case to be an acute surgical emergency whether it be day or night. We do not believe in the conservative treatment of peritonitis and delay operation only long enough to replenish fluids, electrolytes, or blood proteins where such treatment is believed to be indicated. The occasional patient is seen, however in such a critical state that even the slightest trauma under local anesthesia would be fatal here we recommend delay and transfusions. Two such instances occurred during the 1935 to 1939 interval one patient died within a few hours and the other improved sufficiently to be operated upon at the end of 24 hours, only to succumb later.

A case diagnosed as appendiceal abscess when patient is admitted to hospital is delayed if the operator feels the localizing process has been completed but when doubt exists, immediate operation is believed to be safest.

The McBurney incision is routinely employed whenever the diagnosis of acute appendicitis is made and we feel that it has been largely responsible for a nominally low mortality rate. It was used in about 95 per cent of our cases.

The appendix is removed by cautery or the phenol knife and inverted with a linen purse-string suture re-enforced by a Lembert of cat-gut without ligating its base. Simple ligation of the base without inversion of the stump is reserved for those patients with inflammation and resultant thickening of cecal wall, or if application of the pursestring is technically difficult.

In the presence of an appendiceal abscess, when exposure and removal of the appendix increase the possibility of spreading the infection to uninvolved peritoneum, simple incision and drainage are employed with the intention of secondary appendectomy at a later date. Otherwise the appendix is removed and the wound is closed about one or two drains. The soft rubber fenestrated tube has been the drain of choice, since we believe that the establishment of a tract can be obtained best in this manner.

In the presence of peritonitis the usual procedure is to place a drain down to the pelvis and another to the site of the appendix stump. The peritoneum is rarely closed without drainage.

In the simple acute case the wound is closed in layers without drainage, in cases of doubtful localized peritonitis a soft rubber tube or Penrose drain is placed down to peritoneum and the abdominal wall is closed singly about the emerging drain.

The great majority of patients requiring drainage of the peritoneal cavity have been closed after the manner recommended by Dr. John Garlock, which consists in simple closure of the peritoneum about the drains, with the remainder of the wound left wide open. A few of the surgeons have approximated transverse muscles and internal oblique muscles in addition.

In an analysis of such a series of cases as we are presenting, certain criteria must arbitrarily be chosen to classify the various types of lesions so that they may be easily and clearly understood as well as easily and accurately compared with similar groups. It is for this reason that we eliminate the many confusing terms and classify this series of cases of acute appendicitis as recommended by Dr. Mont R. Reid.

Group 1 The simple acute appendicitis. In this variety there is no gross evidence of perforation, the fluid about the appendix if present is not frankly purulent, and a culture of such fluid if taken has been reported as showing no growth.

Group 2 The acute appendicitis with localized abscess formation.

Group 3 The acute appendicitis with peritonitis. This final group includes both those cases of spreading or diffuse peritonitis and those of the localized variety. It is believed that a true knowledge of the extent of a peritonitis is impossible to obtain through an ordinary incision. The impression would vary with the individual surgeon and could be accurately determined only after a very improper operation (6).

In most instances the operator's vivid description of the peritonitis left no doubt that it belonged in this group, but occasionally his description was doubtful and, in such an instance, dependence was placed on a positive culture. When a culture of peri-appendiceal fluid was reported positive for *Bacillus coli* or streptococcus, even though no gross perforation was detected and even if the appendicitis had been described as the simple acute variety, we classified it as a case of localized peritonitis. In the cases of abscess formation or peritonitis, we found that *Bacillus coli* was the causative organism in 83 per cent of cases. Other organisms encountered as etiological factors in their order of frequency were gamma streptococcus and beta streptococcus. Sometimes associated with *Bacillus coli* or with the streptococcus organisms were *Bacillus proteus*, *Bacillus lactis aerogenes*, and *Bacillus mucosus capsulatus*. No anaerobic cultures were done.

In January, 1940, we began using sulfanilamide crystals placed directly into the peritoneal cavity as an adjunct in the treatment of acute appendicitis with perforation and peritonitis. The first few patients were desperately sick, the peritonitis in each instance seemed diffuse in character, and the fluid was frankly purulent and had a fecal odor. The convalescence and cure of these patients was so dramatic, that one could not help but be impressed with the value of the drug used thus.

Fig. Coordinated average blood level curve. This chart includes all patients who received total of grams of sulfanilamide and on whom postoperative blood levels are taken. The number of levels taken on each patient varied from 1 to 8. None of these patients received sulfanilamide after operation by any route. Each of the points on the graph represents time indicated. From these scattered points, curves are drawn which roughly indicate the rate of absorption of the drug and maintenance of the blood concentration.

The technique employed was at first rather crude, consisting in pouring the crystals directly into the depths of the wound with the retractors spread widely apart and lifted in order to give greater depth to the peritoneal cavity. The drug, sterilized only by the chemical company at the time of preparation, was poured directly from the pronylin bottle into a sterile 1-ounce measuring glass held by a suture nurse. If 2 drams of the drug were used, we knew by rough computation previously determined by the druggist that 5.5 grams had been administered.

We later discovered that it could be sterilized without disturbing its crystalline powder form. The crystals were found difficult to manage the minute they struck moisture and in this respect greatly resembled sugar. A moist heat used for sterilization that can penetrate to the drug converts it into a hard rock-like mass on drying for this reason autoclaving is unsatisfactory.

The sulfanilamide is now weighed in the drug room, put into test tubes in 2, 4, 6 and 8 gram quantities and each tube snugly stoppered with cotton. The tubes are then sterilized by placing in an oven, where the heat is maintained at 120 degrees C for one-half hour.

The test tube is a handy container, as it has been the most effective implement for depositing the crystals in the peritoneal cavity. An implement, such as a long handled gall-bladder scoop, which allows blood, serum, or peritoneal fluid to touch the drug, immediately converts the soft dry powder into a wet sticky substance that clings to the applicator.

We have placed varying quantities within the peritoneal cavity. A smaller amount is often placed in the abdominal wall layers during closure, as we have found wound healing aided by this maneuver in the frankly purulent cases. There is no doubt that involvement of the wound thus seems much more limited and localized to the vicinity of the emerging drain. This feature has been such a consistent finding that it is a great temptation to discard the Garlock method of closure.

Postoperative sulfanilamide blood levels have been taken at frequent time intervals. The initial rise is prompt and fairly consistent; the fall in blood level is much more gradual but shows the same consistency (Fig. 1). When the drug is put only in the peritoneal cavity and not in the abdominal wall, the fall is very abrupt. The average peak obtained was 6.9 milligrams of sulfanilamide per 100 cubic centimeters of blood, and the average time at which this point of maximum concentration was reached was 14.7 hours after operation.

The height of the original rise is entirely dependent upon the amount used and also upon the amount which is lost in the presence of a drain. The length of time in which one can expect to get a positive blood level is also markedly influenced by the presence of drains and is in direct proportion to the amount placed in the muscle and subcutaneous layers.

These findings imply that the drug is absorbed from its local storehouse at a definite rate. The greater the amount used and the less it is allowed to be lost through drainage, the higher the possible blood level. It also indicates that the body absorbs the drug much more rapidly from the peritoneum than it does from the muscle or fat.

Draper and Kauer have shown in dogs that, after intraperitoneal use of sulfanilamide, blood level reached its peak in about 6 hours and rapidly approached zero in 65 to 75 hours.

TABLE I

Total cases	Number of cases	
	59	145
Complication	Sulfanilamide in peritoneum	None used
Wound complication	6*	5
Prolonged temperature	7	0
Pulmonary embolus	2	3
Serum in wound	1	0
Fecal fistula (temporary)	2	0
Upper respiratory infection	1	2
Secondary peritoneal abscess	1	1
Jaundice	1	0
Atelectasis	0	3
Phlebitis	0	1
Hematuria	1	0

*This term does not apply to cases of prolonged wound drainage, but indicates those cases showing secondary wound abscess. We feel that too much dependence was placed on the sulfanilamide in these cases, and improper drainage of the wound was performed.

It is our contention that there is a tremendous concentration of the drug locally, many times the amount represented by its blood level, and that the mode of attack against the peritonitis is much akin to an *in vitro* destruction of the bacteria.¹

Postoperative blood levels have been taken in a few cases at 2, 4, 6, 12, 18, and 24 hour intervals, and subsequently at 8 o'clock each morning until the report is completely negative for any trace of sulfanilamide. In others, the levels were taken at sporadic intervals. The impression has been gained that the point of maximum absorption into the blood stream occurs at about 12 hours from the time of its introduction and then steadily declines.

The average adult dosage recommended in case of peritonitis is 8 grams intraperitoneally and 4 grams placed in the abdominal wall layers. A few grams more can be used in the treatment of severe diffuse peritonitis, and less in the treatment of the definitely localized variety. The appendiceal abscess seems to lose the drug more rapidly by drainage, and in this type it is safe to use as high as 20 grams total.

Age and weight are factors which modify dosage, in infants and children we have used one-quarter or one-half the amount employed for the adults. It is safe to calculate the dos-

TABLE II —COMPARISON OF IMPORTANT COMPLICATIONS

Type of complication	1935-1939 (741 Cases)		1940 (204 Cases)	
	No	Per centage of total cases	No	Per centage of total cases
Wound infection	85	11.5	11	5.4
Secondary peritoneal abscess	21	2.8	2	0.9
Atelectasis	16	2.1	3	1.4
Pneumonitis	12	1.6	0	0
Wound separation	8	1.1	0	0
Phlebitis	5	0.7	1	0.5
Pylephlebitis	2	0.27	0	0
Jaundice	1	.13	1	0.5

age on a basis of 175 milligrams per kilogram of body weight.

One of the patients with abscess had a secondary appendectomy about 2 months later. The lack of adhesions encountered and the normal appearance of the peritoneum were striking. This one example adds to our general impression that the drug does not irritate the peritoneum.

We have noticed no definite toxic effects from the use of the drug administered in this fashion except some cyanosis, which, though not a constant feature, is usually evident. The nausea and vomiting, if present, have not been sufficiently distinguishable from that to be expected in a convalescent from an appendectomy.

There have been no cases of leucopenia or agranulocytosis, but there was 1 case of jaundice which was felt to be secondary to the streptococcus peritonitis, as it disappeared under the continued administration of sulfanilamide by mouth (Table I).

Persistent elevation of temperature did occur in a few instances, and in several of these cases it was felt directly attributable to the sulfanilamide.

In those patients in whom sulfanilamide was used the age varied from 1 to 72 years. The lesion in 45 per cent of the peritonitis group could definitely be considered diffuse. Many of these patients were critically ill, and in a few the constitutional condition of the patient and the local findings presented a

¹The Winthrop Chemical Co. Inc. informs us that from 157 to 160 grams of sulfanilamide will dissolve in 100 cubic centimeters of beef serum at 37 degrees C. This approximates what one might expect to take place within the peritoneal cavity in the human and would give under these circumstances a concentration of about 1600 milligrams per cent.

TABLE III
1935-1939

	Cases	Deaths	Mortality %
Peritonitis	566	3	53%
Appendicitis	59	4	6.7%
Intestinal	116	3	26%
Total	741	10	7%

clear picture. We feel that the cure in these instances was nothing short of miraculous.

Sulfanilamide was used in a total of 59 or per cent of the cases, representing each one of our three groups of the disease. In all of these 59 instances it was continued either by rectum or by mouth because of the extremely severe pathological process encountered at operation or the continued critical condition of the patient. The added experience with dosage has led us to believe that a sufficiently large intra-abdominal application indicates the necessity for any continued operative administration.

RESULTS

During the 1935 to 1939 period a total of 741 patients with acute suppurative appendicitis were operated upon, with 10 deaths, a total mortality rate of 7 per cent (Table III). A further analysis of these deaths can be obtained from glancing at the accompanying Table (Table IV) but needless to say the majority were directly attributable to peritonitis. Of the 3 deaths which occurred in the acute group they give a mortality rate which although has been reported considerably lower for this group by other clinics (Table V). One of these deaths was due to a bad rheumatic heart, one to pyelophlebitis and septicemia,

TABLE IV—ANALYSIS OF DEATHS
1935-1939

	Cases
A. Diffuse peritonitis	1
B. Post operative pneumonia	1
C. Pyelophlebitis and septicemia	1
D. Pulmonary embolism	1
E. Rheumatic heart and decompensation	1
F. Acute pericardial cystitis	1
Total	6
Acute	A+C+E = 3
Abscess	A+B+C+F = 4
Peritonitis	6A+B+D = 5

and the third to poor surgical judgment, as an inadequate operation had been performed.

The mortality rates for the abscess and peritonitis group are low as compared generally with statistics from other hospitals.

During 1940 we treated a larger total number of patients with appendicitis than had ever been treated in any previous year (Table VI). This is directly attributed to the fact that it is our first full year with an ambulance.

The proportionate number with abscess and with peritonitis was the same, but the actual number was greater than in any previous year. As a result, we dealt with more critical cases of peritonitis during this period.

There were no deaths from the disease in any one of the three varieties, the impressive mortality rate of zero. Complications were relatively few in the total series (Table I) and there was a noticeable reduction in wound infections and secondary peritoneal abscesses, as compared to the previous years (Table II).

SUMMARY

A total of 741 patients with acute appendicitis was operated upon during the 1935 to

TABLE V—COMPARATIVE MORTALITIES FROM OTHER HOSPITALS

TABLE VI — 1940

Type	Cases	Deaths	Mortality %
Acute	152	0	0
Abscess	21	0	0
Peritonitis	31	0	0
Total	204	0	0

1939 interval The mortality rate varied from 0.53 per cent in the simple acute variety to 11.2 per cent in the perforated appendix showing peritonitis, with a total mortality of 2.7 per cent

Sulfanilamide was applied intra-abdominally in nearly all the patients during 1940 in whom there was real or doubtful involvement of the peritoneum by infection. Complications seemed less frequent and were less severe, the drug in the dosages used had no severe toxic effects generally and failed to show any destruction of tissues locally. The only local effect noticeable was the encouraging rapidity of healing.

In conclusion we wish wholeheartedly to endorse the use of sulfanilamide intra-abdominally when indicated. We do not desire to give the impression that the mortality rate from the disease with its use will henceforth approximate zero, as we feel unusually fortu-

nate in that there were no deaths from embolism or other conditions entirely dissociated from peritonitis. It is our firm conviction, however, that the dramatic reduction in our mortality rate during the year of 1940 was directly due to sulfanilamide.

THE NEUROGENIC FACTOR IN INTESTINAL OBSTRUCTION

R. F. ANTONCIC, M.D. Cleveland, Ohio

HAMPDEN LAWSON, M.D. Louisville Kentucky

THE importance of afferent nerve impulses from obstructed distended intestine is again being stressed. Braun and Borstau were the first to postulate a neurogenic theory for death in obstruction, according to which noxious stimuli reach the brain and produce failure of vasomotor and other centers. Whipple, Stone, and Bernheim observed that the duration of life in their experimentally obstructed dogs was directly proportional to the degree of distention but considered absorption of toxins the cause of death. Dragstedt found that the toxemia was relieved and the chlorides rose in the blood when the obstructed loop was aspirated through the abdominal wall. He considered distention merely an accessory factor which damaged the intestinal mucosa permitting bacterial toxins to be absorbed. Burget et al. noted that a sick dog refusing all food would often eat eagerly 30 minutes after an obstructed loop was aspirated. He decided that death is due to loss of chlorides in the vomitus and that the vomiting is due to reflex nausea and pain from the distended loop rather than to absorption of toxins. Herrin and Meek (10) placed balloons in Thiry Vella loops. The balloons were maintained at a constant pressure of 50 to 80 millimeters of mercury. Fourteen dogs thus treated died in 8 days. The symptoms and blood changes were those of acute intestinal obstruction. Herrin and Meek pointed out that the beneficial effect of saline injections, re introduction of vomitus and aspiration of closed loops might all be explained by dilution, neutralization, or withdrawal of toxin. The authors thus disposed of the toxin theory, since death occurred despite free drainage of Thiry Vella loops. By administering 30 cubic centimeters of 10 per cent sodium chloride daily these workers kept a dog alive for two

14-day periods of distention. A third period of distention without salt resulted in the death of the dog. Meek and Herrin then denervated similar draining loops. Of 8 animals thus prepared 3 endured the distention for 20, 21 and 23 days, respectively with no symptoms and normal blood chemistry. Four others showed "undoubted protection. They concluded that distention causes reflex vomiting and inhibition of appetite and as a result death occurs from unbalanced chloride loss.

Ender and Herrin divided the jejunum 25 centimeters from the ligament of Treitz, inverted both ends, and anastomosed the distal end to the stomach or duodenum, thus producing complete simple obstruction of the jejunum. The fluid from the obstructed bowel returned to normal bowel so that there was only slight loss from vomiting. Four dogs lived 8 days (perforated) 2, 4 and 6 weeks, respectively. Of two denervated animals, one was without symptoms for 16 days and then died on the seventeenth day within a few hours of the onset of symptoms. The other dog was reported normal on the eighteenth day of obstruction. Since all dogs survived far beyond the 8 days (except the one with perforation) reported for simple jejunal obstruction, the authors concluded that the rôle of toxemia in acute obstruction seems to be of less importance than chemical or nervous factors.

Taylor Weld and Harrison introduced a balloon into the duodenojejunum with a by pass of heavy walled rubber tubing. In this manner the authors were able to distend the intestine with pressures of 60 to 110 millimeters of mercury without completely blocking the lumen. They showed fluoroscopically that a barium meal passed through the rigid tube beside the distended balloon. Dogs thus prepared vomited only occasionally the blood chlorides remaining near normal yet all died within 54 hours. However if the segment of

bowel holding the balloon was denervated, the dogs survived the distention about 72 hours, dying of peritonitis induced by balloon erosion of the gut. Taylor and his co-workers believe distention per se is the primary cause of death in intestinal obstruction, i.e., afferent nerve impulses from the distended viscus cause the vomiting, fall in pressure, and collapse of acute intestinal obstruction.

Best and Taylor stress that acute distention of even a small intestinal pocket as in Richter's hernia in which the intestinal lumen is not entirely occluded, leads to all the symptoms of intestinal obstruction. Wangenstein and Rea by excluding swallowed air (cervical esophagostomy) and preventing distention in dogs with complete occlusion of the terminal ileum spared these animals for an average of 36 days (giving 1500 cubic centimeters of 1 per cent saline daily and occasional blood transfusions). These authors concluded that the mechanical factor of distention and not a toxic factor accounts for the lethal issue in ileal obstruction.

Fine, Rosenfeld, and Gendel resected the celiac ganglion and all the splanchnic nerves (and/or the subdiaphragmatic vagus nerves) in cats, checking the completeness of the denervation at autopsy on the death of the animals. They concluded that exclusion of the extrinsic nerve supply does not influence the survival time. However, Herrin and Meek (11) found vagotomy, splanchnicotomy, and lumbar sympathectomy permitted the distention of Thiry-Vella jejunal fistulas without any symptoms in 6 dogs. Bilateral splanchnicotomy and lumbar sympathectomy prevented vomiting and to some extent the depression, but anorexia appeared.

Our observations indicate that denervation does exert a protective effect and by using non-draining loops distended by the gas and secretion resulting from the obstruction alone, we produced the ideal medium for absorption of any specific toxin formed in intestinal obstruction.

METHODS

Obstruction of the first portion of the jejunum, 15 centimeters from the ligament of Treitz, was produced by the technique of

Fig 1 Tracing of denervated non draining jejunal loop, obstructed for 12 hours. Top tracing, respirations, timer, 4 second intervals, scale, pressure in centimeters of water.

Stone, Bernheim, and Whipple, i.e., resection of a 10 to 12 centimeter segment, inversion of the ends to form a closed loop, and then re-establishing the continuity of the gastrointestinal tract by an end-to-end anastomosis. Numerous workers have shown (6, 5, 13) that death occurs more rapidly under these conditions than if the bowel is obstructed by a single ligature at this level. Denervation of these obstructed loops was effected by dissecting out the central vessels, cutting all other structures and painting the vessels with 20 per cent phenol in 15 dogs. Denervation was produced in 6 dogs by infiltrating the mesenteric pedicle with 95 per cent alcohol (or ether, 2 dogs).

In 6 dogs the motility of the obstructed denervated loops was studied by inserting balloons connected to water manometers and recording tracings of pressure changes on smoked paper. These observations were made on unanesthetized animals at variable intervals of obstruction.

Animals were operated upon under intraperitoneal sodium pentobarbital anesthesia. No special postoperative care was given. Water was placed in the cages next day and the stock diet the following day.

RESULTS

In the 6 dogs prepared for motility studies of denervated obstructed loops, the average of the maximum spontaneous pressures is 27

centimeters of water which is not significantly different from the average (26.8 cm.) of non-denervated obstructed loops (1). Our observations show that the motility pattern of denervated obstructed intestine is similar to non-denervated obstructed intestine. Denervation, then, does not interfere with the building of increased pressures in obstructed loops (Fig. 1).

Of 10 non-denervated control animals, all died in 36 hours to 7 days, the median being approximately 72 hours. At autopsy 7 loops were perforated and 3 were distended. Of 23 denervated dogs 11 lived and 12 died (3 to 4 days). At autopsy in the animals which died every loop (but one) was perforated and death was attributed to peritonitis.

The dogs protected by denervation lived from 3 weeks to 4 months. Five dogs were killed when normal for 4 to 8 weeks. These animals did not vomit after the first day or two ate voraciously were active and alert. When killed, the examination revealed that 3 dogs had collapsed loops containing 10 to 20 cubic centimeters of gray mucus fluid while two had markedly distended loops, a culture from one yielding a pure growth of streptococci (hemolytic and non hemolytic). The contents of these loops was fecal in character with very foul odor. Six animals died in from 3 weeks to 4 months. These were entirely normal until 1 to 2 days before death when they became listless, vomited and refused to eat. Four dogs dead of internal herniation and volvulus apparently had acute accidents avoidable with better surgical technique. Why two animals should suddenly develop generalized gas gangrene after 3 and 4 months of normal livelihood is not apparent. It is conceivable that the anaerobic bacteria finally got a foothold and produced active infection. These dogs were tremendously distended and solid organs, like liver and spleen, were crepitant and literally bubbling with the gas.

EVALUATION

Denervation of an obstructed non-draining loop of intestine apparently will protect a dog against death for 3 or 4 months if the loop does not perforate. If perforation occurs the animal dies of peritonitis. It is not apparent

why some loops perforate while others with stand marked distention for long periods. It was noted in the non-denervated controls that 3 of the dogs died with distended non-perforated loops. It is well known that death frequently occurs from distended discolored bowel which has not perforated. It has been shown (9) that death in closed loops, even when strangulated, can occur without bacteria in the peritoneum or the blood stream.

Herrin and Meek (10) have not disposed of the toxin theory by draining the loops to the outside since the toxin is believed by advocates of the toxin theory to be formed in the mucosa and absorbed under the influence of the distention directly into the veins and lymphatics. Our closed loops should be ideal for absorption of toxins under the pressure produced by the obstruction itself but dogs with denervated loops lived unless the loops perforated. That denervation eliminates a neurotoxin is unlikely since animals dying of closed loop obstruction do not die of progressive paralysis; also several animals were saved with nerves spared but rendered nonconductive by ether or alcohol. That elimination of lymphatics is a protective factor is not probable since these are quickly reformed.

The data show that the protective effect of denervation is not due to altered motility.

SUMMARY

1. Dogs were prepared with closed loop obstructions, 10 serving as controls while 23 were denervated.

2. Balloon studies of intestinal motility were done in 6 unanesthetized dogs with denervated closed loop obstructions.

3. Denervation does not significantly alter the motility of obstructed loops.

4. Denervation of an obstructed non-draining jejunal loop prolongs life, dogs dying after 3 or 4 months of generalized gas gangrene. There is, therefore, no evidence for the existence of a special toxin of intestinal obstruction.

FAT EMBOLISM

A Clinical and Experimental Study

CARLO S. SCUDERI M.D. Ph.D. F.A.C.S., Chicago, Illinois

SINCE over 600 known references to fat embolism are found in the literature only the high lights of the literature that pertain to the experimental and clinical work to follow will be presented. Clinically fat embolism is very difficult to substantiate conclusively. This difficulty is really not the fault of the medical profession but is due to the nature of the disease, which makes its incontestable recognition very problematic. For this reason I have spent most of my study on the diagnostic phase of this malady. Those desiring complete reviews on the subject should refer to articles by Warthin 1913 Scuderi (42) 1934 and Groszkloss, 1936

HISTORICAL

As early as 1669 Lower had injected milk intravenously in dogs, and this was probably the beginning of our knowledge of fat embolism.

Magendie during the years 1821 and 1836 did some experimental work on lipemia and its effect on the circulation in animals. His description of the experimental introduction of liquid oil into the venous circulation is classic.

Zenker 1862 observed the first fat emboli in the pulmonary capillaries of a man following a severe crushing injury to a railroad worker. The pulmonary capillaries were found to contain a great many emboli of fluid fat. He thought that they occurred by aspiration through the gaping veins from the stomach of the patient.

Scriba in 1880, reviewed all the cases up to date and then added 34 cases of his own. He also conducted animal experiments and brought forth many clinical and pathological points which had previously been obscure. Most of our modern textbooks dealing with the subject of fat embolism are based upon

the statements and conclusions which he drew. However years have shown that some of his opinions were erroneous. Of 177 cases of fat embolism which he collected in only 14 instances could fat embolism be regarded as the cause of death, and some of these he regarded as doubtful.

Lehman and Moore (1927) by *in vitro* experiments showed that histamine extracted from necrotic muscles, produced a very rapid disintegration of the fat emulsion of normal blood serum. They concluded that fat embolism might be readily produced in the bone marrow on a non-traumatic basis purely by the absorption of histamine from injured body tissue, into the blood stream. They also found that intravenous ether produces fat embolism of the lung by dissolving the normal emulsified fat of the lungs, and, when the ether vapor tension is lowered by evaporation into the alveoli, the free fat becomes visible microscopically in the blood.

ETIOLOGY

The experimental work done on the etiology of fat embolism has been considerable and, in many instances, has led to much contradiction and confusion.

Males are many more times affected than females, the proportion being about 8 to 1. The youngest case on record, a newborn, was reported by Nicod. The greatest incidence is during the fourth decade of life. Rarely does fat embolism occur in children because the fat in the bone marrow is insufficient up to the fourteenth year (Speed). Landois, in an excellent article on the subject, states that he found mostly palmitin and stearin in children and infants, with a smaller proportion of the more fluid olein. At body temperature oleic acid is quite fluid and is more easily absorbed than the more viscous palmitic and stearic acids. For this reason fat embolism is not so common in children.

It appears as though alcoholics are more predisposed than nonalcoholics. Perhaps this is due to the instability of the fat emulsion in the serum produced by the frequent dilution with the fatty solvent after a "debauche" (Cubbins).

Lehman and Moore calculated the amount of fat in the bone marrow of a femur and found it to be approximately 65 cubic centimeters. By experimental study with cottonseed oil they found that, should man be able to tolerate as much oil in the blood stream as a dog, 120 cubic centimeters would be required for a lethal outcome. This is based on two assumptions: first, that cottonseed oil does not materially differ from bone marrow fat, and, second, that man, as well as dogs, can tolerate free fat in the blood. If this be true, all the fat in the bone marrow of a femur could be well tolerated. After a great deal of controversy as to whether the fat is carried by the blood or lymph vessels, the present opinion seems to be that most of it is carried by the veins while a smaller part may be carried by the lymphatics.

It is interesting to note that experimental animals can be made to build up a resistance to experimental fat embolism by repeated small injections of fat. This work was done primarily by Paul and Windholz, and later by Domanig. They found that such animals could withstand many times the lethal dose. No fat droplets could be found free in the blood serum of these animals. Evidently they are rapidly destroyed by a newly formed, unknown substance.

PATHOGENESIS AND PATHOLOGY

After the injury to the bone marrow fat or adipose tissue, there is a disintegration of the supporting fibrous tissue with liberation of the fat. Naturally there are ruptured blood vessels in the vicinity of the injury. The arteries squirt more blood into the area, thereby increasing the pressure, while the veins remain open and absorb the fatty mixture by venous suction (Miloslavich), particularly if their consistency is more or less fluid.

Gauss (20) brings out the point that fat embolism is more common in fractures than in any other condition because the veins are

encased in a bony wall and hence cannot collapse as elsewhere in the body, thus they remain wide open for the admittance of the fatty mixture. This process may take place immediately or proceed for some time until coagulation occurs. The pathology of this condition involves all the organs and is too well known by all to be discussed in this very brief résumé.

Lehman and McNattin found at postmortem examination that fat embolism is present in the lungs of about 50 per cent of unselected cases. These men have conclusively shown that anatomically the diagnosis of fat embolism as the cause of death cannot be safely made.

Wright found at postmortem examination fat embolism present in 52 of 100 consecutive cases, in the majority of which patients did not suffer from fractures or contusions from falls or accidents. This author also helps to substantiate the contention that postmortem findings of fat embolism are not pathognomonic evidence of violence.

Carrara found fat embolism present in 22 per cent of cardiovascular renal diseases and 44 per cent of burns. Catsaras reported fat embolism in the lungs of 18 of 67 cases of post-influenzal pneumonia. To add to the already great confusion on the subject, acidosis, phlegmonous gastritis, acute pancreatitis, chronic tuberculosis, menstrual suppression, hepatitis, splenitis, and tuberculous pneumonia have been mentioned. In fact, almost all diseases, poisonings, and injections to which the body has been subjected have been reported in the literature as having caused fat embolism at one time or another.

Vance, in 1931, wrote a very comprehensive paper on fat embolism from a pathological viewpoint, which is a classic on the present literature on the subject.

SYMPTOMS

There is no clinical correspondence between the apparent injury and the degree of resulting lipemia. Injuries which are apparently identical may in one individual be followed by a fatal lipemia, while in another individual the same injuries may cause but a slight disturbance.

FAT EMBOLISM

A Clinical and Experimental Study

CARLO S. SCUDERI M.D. Ph.D. F.A.C.S. Chicago, Illinois

SINCE over 600 known references to fat embolism are found in the literature only the high lights of the literature that pertain to the experimental and clinical work to follow will be presented. Clinically fat embolism is very difficult to substantiate conclusively. This difficulty is really not the fault of the medical profession but is due to the nature of the disease, which makes its incontestable recognition very problematic. For this reason I have spent most of my study on the diagnostic phase of this malady. Those desiring complete reviews on the subject should refer to articles by Warthin, 1913; Scuderi (42) 1934 and Groskloss 1936.

HISTORICAL

As early as 1669 Lower had injected milk intravenously in dogs and this was probably the beginning of our knowledge of fat embolism.

Magendie, during the years 1821 and 1836 did some experimental work on lipemia and its effect on the circulation in animals. His description of the experimental introduction of liquid oil into the venous circulation is classic.

Zenker 1862 observed the first fat emboli in the pulmonary capillaries of man following a severe crushing injury to a railroad worker. The pulmonary capillaries were found to contain a great many emboli of fluid fat. He thought that they occurred by aspiration through the gaping veins from the stomach of the patient.

Scribe, in 1880, reviewed all the cases up to date and then added 34 cases of his own. He also conducted animal experiments and brought forth many clinical and pathological points which had previously been obscure. Most of our modern textbooks dealing with the subject of fat embolism are based upon

the statements and conclusions which he drew. However years have shown that some of his opinions were erroneous. Of 177 cases of fat embolism which he collected, in only 14 instances could fat embolism be regarded as the cause of death and some of these he regarded as doubtful.

Lehman and Moore (1927) by *in vitro* experiments showed that histamine extracted from necrotic muscles, produced a very rapid disintegration of the fat emulsion of normal blood serum. They concluded that fat embolism might be readily produced in the bone marrow on a non-traumatic basis purely by the absorption of histamine, from injured body tissue, into the blood stream. They also found that intravenous ether produces fat embolism of the lung by dissolving the normal emulsified fat of the lungs and, when the ether vapor tension is lowered by evaporation into the alveoli, the free fat becomes visible microscopically in the blood.

ETIOLOGY

The experimental work done on the etiology of fat embolism has been considerable and in many instances, has led to much contradiction and confusion.

Males are many more times affected than females, the proportion being about 8 to 1. The youngest case on record, a newborn, was reported by Nicod. The greatest incidence is during the fourth decade of life. Rarely does fat embolism occur in children because the fat in the bone marrow is insufficient up to the fourteenth year (Speed). Landolt in an excellent article on the subject, states that he found mostly palmitin and stearin in children and infants, with a smaller proportion of the more fluid olein. At body temperature oleic acid is quite fluid and is more easily absorbed than the more viscous palmitic and stearic acids. For this reason fat embolism is not so common in children.

From the University of Illinois, College of Medicine.

It appears as though alcoholics are more predisposed than nonalcoholics. Perhaps this is due to the instability of the fat emulsion in the serum produced by the frequent dilution with the fatty solvent after a "debauche" (Cubbins).

Lehman and Moore calculated the amount of fat in the bone marrow of a femur and found it to be approximately 65 cubic centimeters. To add to the already great confusion on the subject, acidosis, phlegmonous gastritis, acute pancreatitis, chronic tuberculosis, menstrual suppression, hepatitis, splenitis, and tuberculous pneumonia have been mentioned. In fact, almost all diseases, poisonings, and injections to which the body has been subjected have been reported in the literature as having caused fat embolism at one time or another.

Vance, in 1931, wrote a very comprehensive paper on fat embolism from a pathological viewpoint, which is a classic on the present literature on the subject.

SYMPTOMS

There is no clinical correspondence between the apparent injury and the degree of resulting lipemia. Injuries which are apparently identical may in one individual be followed by a fatal lipemia, while in another individual the same injuries may cause but a slight disturbance.

The onset may be sudden within a few hours of the injury but usually does not become manifest until the third or fourth day. Once the symptoms set in, they may vary from a slight irritability and excitability of the patient to maniacal periods associated with high grade delirium and death. The symptoms, if watched carefully, have a tendency to be cyclic, corresponding to the emboli passing from the pulmonary circulation to the systemic, and gradually returning. Many of these cases appear to be doing nicely when gradually they begin to show some signs of nervousness and excitability. At this time the pulse and temperature begin to show a slight rise. The respirations show a more rapid rise than the pulse, and even early in the symptomatology may be dyspneic. As more capillaries are obstructed in the lungs, the dyspnea increases correspondingly. Cyanosis may or may not appear depending on the extent of pulmonary impairment. Gradually a passive congestion occurs in the lungs and moist rales are audible over the bases. A cough begins to appear and is of a productive nature rarely blood-stained however. For this reason, many such cases are diagnosed as bronchopneumonia.

As the pulmonary arterial pressure increases the heart must beat faster in order to overcome the circulatory resistance. The pulse becomes faster and stronger and the blood pressure begins to rise. Should the resistance in the pulmonary circulation increase or remain great, the heart before long begins to weaken. Its rate increases while its force decreases. The blood pressure correspondingly begins to fall. Should some of the emboli lodge in the coronary vessels, then the cardiac failure comes on much more quickly. Before long the pulse becomes imperceptible, the arterial pressure falls, the venous pressure rises and the picture of deep shock and cardiac failure appears.

The temperature varies from subnormal to 106 to 107 degrees F., depending on whether or not the heat regulating center is disturbed by the emboli. The usual temperature during the height of the disease, is about 103 degrees. In terminal cases the temperature often rises much higher.

Petechial hemorrhages (Ryerson in 1916) may appear in the skin as in any other disease in which the embolic phenomena predominate. However, due to the fact that the capillaries are not actually occluded as in bacterial endocarditis but the circulation is greatly slowed down because of the increased viscosity of the blood (Gause, 19) they are rare. LeCount and Gauss published the results in 14 cases of death following fat embolism upon which postmortem examinations had been done. A study of the clinical symptoms of these cases is very instructive as it gives us some idea of what occurs in milder cases which do not have an *exitus letalis*.

All of these patients passed from consciousness to a restless stage. In 12 this took the form of delirium, 11 becoming so violent as to require restraint. Eleven passed from delirium to the comatose state. In all 14 cases dyspnea was present, and also an associated increase in respiratory rate, the average being 53 respirations per minute. Two cases developed Cheyne Stokes respiration. 4 suffered from air hunger. 3 developed a marked cough. The pulse became weak and shallow and averaged 153 per minute. Involuntary passage of urine and feces occurred in 12 and in the 2 others the records were incomplete. At the time of admission the temperature was either normal or subnormal and then rose to an average of 105.2 degrees F. for the 14 cases. The time that they lived varied from 2 to 17 days, with an average of 6 days.

DIAGNOSIS

The majority of cases of fat embolism are so mild that they do not cause symptoms, or so severe that death results in a few days from involvement of the lungs or the brain. During life the diagnosis of fat embolism is justified only if there is a history of an injury with the typical clinical manifestations.

The incubation period varies from a few hours from the time of accident to 3 or 4 days. It is a good point to remember Dennis' rule in this respect, regardless of the exceptions: shock 3 hours fat embolism, 3 days pulmonary embolism, 3 weeks (Speed).

Additional confirmatory signs are the presence of fat in the urine, the demonstration of

SCUDERI FAT EMBOLISM

fat emboli in the retinal vessels by the ophthalmoscope, and the appearance of petechial hemorrhages in the chest, shoulders, and neck. The presence of the large circular cells of Liting and Martin or the fat globules of Warthin in the sputum are not pathognomonic signs, as they are found in conditions other than fat embolism. As a rule, fat embolism is rarely diagnosed from clinical signs and symptoms, it is most often discovered accidentally at necropsy.

In the differential diagnosis delirium tremens, skull fractures, bronchopneumonia, and shock must be most seriously considered.

PROGNOSIS

The prognosis in fat embolism should always be reserved because some of the patients who appear to be coming along well suddenly grow worse and die. As to life, most of the patients recover, but due to the fact that only the fatal or very sick cases are diagnosed and the mild cases overlooked, most people have the reverse idea.

TREATMENT

As fat embolism in fractures is not of common occurrence, and when it does occur is rarely diagnosed, one can understand why reports regarding the treatment of this complication are not very illuminating. Grondahl states that a terminal result occurs in but 1 of every 3,000 cases of fracture, and that death attributed to fat embolism in fracture cases occurs in only 1 per cent of the cases.

Much experimental work has been done on the prophylaxis, with much forethought and logical thinking. Wells, Ryerson, and Caldwell and Huber have shown that a tourniquet, if used during the operation or manipulation, reduces the possibility to a minimum, especially if it is allowed to remain in place for an hour after the operation. Simonds found that etherized dogs were more susceptible to fat embolism than were those anesthetized by non fat solvents. This is a point of some importance and if another anesthetic which is not a fat solvent can be used as efficiently and safely it should be given preference.

Warthin advises the following prophylactic management: 1. Avoidance of unnecessary or

rough handling of patients 2. Immediate splinting and early reduction of all fractures (Tanton) 3. In orthopedic operations use of a saw in preference to the chisel, if possible (Lever) 4. Slow removal of Esmarch's bandage (Buerger, Aberle)

Reiner advises canaliculizing the vein, allowing the first blood after removal of the constrictor to flow out. Czerny, and 50 years later Wegelin, also advocated the injection of sodium carbonate, probably with the idea of forming a soluble soap. This method has fortunately received but little support. All experimental animals died under this regimen.

The active treatment of this condition is very poor, and many of the suggested methods are not only theoretically, but also practically, in error.

Czerny advises venesection to lessen the venous congestion. Schanz believes physiological salt solution both intravenously and by hypodermoclysis to be of benefit, while Bissell believes that such a procedure is contra-indicated because of increased pressure to the right heart.

Wilms suggested drainage of the thoracic duct. Fritsche found experimentally that if this was done at the first appearance of the symptoms it helped. Grondahl found that even ligation of the femoral vein and removal of the inguinal glands did not prevent fat embolism.

Wilms also advised incising the area of fracture and combating its origin by evacuating the blood and fat.

Pituitrin, pituglandol, caffeine, coramine, morphine, and sympatol have been suggested in the active treatment as they have been found both experimentally and clinically to produce a steady fall of blood fat.

VALUE OF BLOOD CHEMISTRY AND PHYSICAL MEANS OF QUANTITATIVE BLOOD FAT DETERMINATION

Since the problem of fat embolism has to do with the presence of fat droplets in the blood stream, it was thought that quantitative blood fat determinations would be of material aid in its diagnosis. For this reason the known methods were looked up and studied in great detail.

Kumagawa and Suto described a saponification method in 1908. Bang in 1918 described an extraction method, which however is not accurate enough for a truly scientific method. Bloor, Pelkan and Allen (6) first brought the nephelometric method to the foreground in 1927. Later in 1928 Bloor (5) published an improved method. Stoddard and Drury described a titration method in 1929.

After a careful study, counsel was sought from several very well known physiological chemists and all agreed that the methods were beyond the capacity (or ability) of the average part-time chemist, and even when the determinations were done in well equipped laboratories by properly trained men, the variations were too great to be of real diagnostic value. For the present at least, the outlook along these lines is unfavorable.

Clinical investigation in the serological department of the Cook County Hospital has revealed many blood serums of almost cream-like appearance. These were found in diabetic comas, lipid nephrosis, and lactating post partum women. In spite of the fat content of the blood having reached this startling height, these cases revealed no manifestations of fat embolism. Some investigators have found diabetic coma cases to have reached a concentration of total lipoids in the blood of 26 per cent (Bantlin) compared with the normal of 0.4 per cent. These observations, therefore, have conclusively proved to the author that it is not the total fat content of the blood which we should be interested in, but the state in which this fat is found. Should it be in the form of a stable emulsion, no fat droplets are present in the blood, hence no embolism can occur. On the other hand, the corpuscular fat content is of all importance as it causes the occlusion of the vessels giving the embolic phenomena. Unfortunately only 5 per cent of the total fat content of the blood is found in this form. If one considers that the total fat content, as has been stated before is only 0.4 per cent, the figure of the corpuscular percentage almost approximates zero. Therefore it stands to reason that any total chemical method for determining increases or decreases of this element would be far beyond the scope of quantitative chemical determinations as the

percentage of error by our best present day methods would be too great.

Other fields of experimental work were searched for possible aid in these determinations. The use of the spectroscope was suggested. However it has been stated that the fat concentration was too small to produce any appreciable variations.

At a later date the possibility of the use of electroconductivity to determine fat content changes in blood serum was considered but this method and also the use of the polariscope has been found to be of negative value and henceforth dropped.

RESULTS OF DARK FIELD EXAMINATIONS OF THE BLOOD AND FRESH SMEARS OF RECENT FRACTURES AND CONTROL CASES

Edmunds first described the dark field examination of the blood for fat particles in 1877. Further work along these lines was carried on by Neumann in 1907. Gage and Fish (18) in 1924 published a most excellent article upon this subject, on investigative work on fat absorption and metabolism in the lower animals. Gage (17) was the first to give these microscopic particles the name of chylomicrons, 1920 meaning that they are one micron in diameter and are composed of chyle.

The study of 25 miscellaneous blood serums from the medical wards of the Cook County Hospital, was undertaken as a control study. No variations from the normal were found. Several cream like blood specimens from a lactating postpartum woman revealed a few interesting observations. In spite of a cholesterol of 335 milligrams, and a milky appearing serum, no actual fat droplets could be found, a fact showing the marvelous stability of a serum fat emulsion.

As the average blood cell is 10 microns in diameter it has been estimated that in order to occlude the finer capillaries of the lung the fat droplet must be at least 12 to 15 microns in diameter. In none of the control cases was this found.

In order to show the feasibility of this diagnostic method in embolic cases, olive oil was injected intravenously in a dog. Five cubic centimeters were used, and it was injected slowly. Two minutes later with a clean

SCUDERI FAT EMBOLISM

syringe and needle, 1 cubic centimeter of blood was removed from the opposite leg, and a drop was examined under the dark field. Large ameba-shaped droplets of olive oil could be easily demonstrated, at least twice the diameter of an erythrocyte.

Twenty-five fresh fracture cases from the service of Dr William R. Cubbins were now selected. All were suffering from major fractures from 3 to 144 hours from the time of accident. One whole blood and one centrifuged serum specimen of each patient was examined. No difference was found between the specimens except that the centrifuged serum was easier to examine due to the lack of interference of a large number of blood cells.

No actual fat droplets were found. I am of the opinion that patients suffering from true fat embolism will show droplets in great number, and that this method will be of a real diagnostic aid.

TECHNIQUE OF URINE ANALYSIS IN FAT EMBOLISM

In the study of this problem, several hundred urine specimens have been examined for the presence of fat in the urine of suspected cases. After a period of time, it was found that this apparently simple investigative phase of the problem offered an interesting physical phenomenon which heretofore has evidently not been emphasized, and for this reason I undertook its investigation.

That fat is excreted by the kidneys into the urine in cases suffering from fat embolism is well known and often spoken of in the literature. Unfortunately, however, its detection is difficult because of one very elementary physical phenomenon, and that is that the fat droplets float on the surface of the urine, and therefore are not excreted from the bladder unless the last few cubic centimeters of urine are expressed. For this reason many urine examined which contain fat are negative because of this simple oversight.

To prove conclusively this contention, two flasks were used to carry out this experiment *in vitro*. The setup used is illustrated in Fig. 1. The flask above represents the kidney, while the one below, the bladder. These are

Fig. 1. Set up used in experiments. Genito-urinary system *in vitro*.

connected by a rubber tube representing the ureter. A second tube from the lower flask represents the urethra. The fluid was permitted to run very slowly from the top flask to the lower, and fine droplets of oleic acid and also olive oil were injected into the tube close to the top flask with a hypodermic syringe. In this manner there existed a visual genito-urinary system. It was noticed that as the fluid accumulated in the lower flask, the fat droplets rose to the top. (In both the *in vitro* and clinical experiments 2 cubic centimeters of oleic acid were used, divided into small droplets by simple shaking with water.)

After the lower flask was filled, the pinch clamp on the rubber tube representing the urethra was removed, and the fluid permitted to flow out. The entire contents of the flask, with the exception of the last few cubic centimeters of fluid, were absolutely fat free. Both urine and plain tap water were used as the fluid in the *in vitro* experiment, and the physical phenomenon was found to be the same.

In order to prove conclusively what was so well demonstrated *in vitro*, the experiment was carried out in the human. With the co-operation of Dr P. Nelson of the urology department, the pelvis of the kidney was injected with 2 cubic centimeters of sterile oleic acid in cases following retrograde pyelography. Four cases were used, 2 males and 2 females.

Two to 3 hours after the fat injection in the pelvis of the kidney, the males were

structed to pass the urine into 5 to 7 flasks, urinating not more than two fingers' depth in each. In both cases, the last flask contained all of the oleic acid while the others were absolutely fat free. Due to the difficulty of collecting the divided urine specimens in the female they were catheterized with glass catheters. In both cases the urine flow ceased without evidence of any fat floating in the flasks, but when the patient was compelled to sit up then the oleic acid filled the glass catheter and not another drop of urine was expressible.

A CONTROL STUDY OF THE URINE AND BLOOD EXAMINATION IN NON EMBOLIC CASES

As far as one is able to determine from the literature the study of the urine and blood serum in normal cases and fresh fractures has never been done. For this reason the following work has been carried on to see whether or not free fat is found in normal control cases.

Two hundred miscellaneous hospital cases were used for the urine examination. In this series only ambulatory male patients were used because of the greater ease in collecting the urine specimen. Great care was exercised in this work to have the patient empty his bladder completely. Unless all of the urine of the bladder is collected, the floating fat droplets will not be expelled, and hence the urine examination would convey the wrong conclusion.

The urine specimens were collected and placed in a cold place overnight. The next morning the surface of the urine would be carefully examined for floating fat droplets.

Any questionable droplets were removed, stained with Sudan III and examined microscopically. In this entire series not one case showed any free fat.

The serology department of the Cook County Hospital was kind enough to permit the unlimited use of the blood serums sent to them for Wassermann tests. Each specimen was labeled centrifuged and then placed in the refrigerator overnight. The following morning each tube was carefully examined. All questionable droplets or debris were stained and examined microscopically. On 5 occasions definite fat droplets were found floating on the surface. However the findings proved only that the needles had been kept in liquid petrolatum in each case and evidently the boiling did not dislodge the oil from the inside of the needle but when the blood was drawn for examination the oil found its way into the specimen.

Eleven of these cases showed a chylous emulsion which rapidly found its way to the surface. This is physiological, as any blood serum drawn within an hour or two after the ingestion of any fatty material presents this phenomenon. In each of the cases cited here in the contention mentioned was found to be correct.

Fifty fresh fracture cases were next studied. Only male patients suffering from major fractures were examined. The duration of the fractures was from 1 to 7 days. The urine was collected by having the patient in either the sitting or standing position and then having him completely evacuate the bladder. Ten cubic centimeters of blood were then drawn from the arm and both specimens were centrifuged and examined. The urine residue was stained with Sudan III and examined microscopically. Occasionally casts were found but in not one instance could fatty casts be found as Riedel described as being present in the urine of 42 per cent of cases with fresh fractures.

The casts were no more numerous nor in any way different from the casts found in any group of urine specimens. Not one specimen of blood serum or urine showed any evidence of free fat droplets. A résumé of these cases is given in Table I.

FAT EMBOLISM

THE VALUE OF CHEST PLATES IN ITS DIAGNOSIS
AN EXPERIMENTAL STUDY

Jirka and Scuderi in 1936 showed for the first time the value of chest plates in the diagnosis of fat embolism

Eleven dogs were used in the experiments, selecting whenever possible an animal weighing close to 12.5 kilograms. Sterile oleic acid was given intravenously to 6, and sterile olive oil to 5 of the animals. Varying doses were used in each experiment.

Due to the research of Landois, who found that olein was the largest component of bone marrow fat, it was decided to try both oleic acid and olive oil in our experiments. The former, being the acid of the trioleate and easily obtainable, was first used. However, as it is toxic and probably unites with the alkaline radicals in the blood stream to form a soap in the chemical sense of the term, olive oil, which is a neutral oil and non-toxic in smaller quantities, was used as a control. It was found that 0.33 cubic centimeter of oleic acid per kilogram of body weight was sufficient to produce death, while 2.2 cubic centimeters of olive oil per kilogram of body weight were required to produce death in dogs. The physical properties of both were similar in that their viscosities were nearly equal and both produced like droplets when emulsified. First the technique for x-ray films of the chest of a dog had to be worked out. Once the plates began to be uniformly good, the oily substances were injected. By taking films before and after the injections, we were able to compare the lung fields, taken in each instance with the same technique.

Figure 2a shows the normal lung field of one of the animals. The lungs are relatively clear, except for the usual hilar clouding. Figure 2b was taken twenty minutes after the injection of 6 cubic centimeters of sterile oleic acid. The lung fields now appear more or less cloudy, of a diffuse, even nature. No patches or increased opacities are noted. The heart shows no enlargement when measured by the superimposition of the films. The following morning the dog was found dead, *rigor mortis* being present. The thoracic organs were removed and roentgenographed *in toto*. The

lungs showed the lack of air. Gross appearance and cut section simulated liver, or the hepatization found in cases of bilateral pneumonia. Palpation revealed no crepitant areas.

Microscopic sections were made and were examined by Dr. Benjamin Nieman of the pathology department of the Cook County Hospital. He described the lungs as being typical of a drowned animal, due to the marked edema of the epithelial cells lining the alveoli, and the clear serous filled alveoli. With Sudan III stain the fat filled capillaries were readily demonstrated.

Figure 3a is of another animal prior to any experimentation. Twenty-five hours after the injection of 2 cubic centimeters of sterile oleic acid, the second film was exposed, Figure 3b. The animal at that time appeared perfectly well and quite normal in every respect. The identical technique was used in both films. Close examination reveals the same diffuse haziness of both lung fields, as seen in the other set of pictures.

Figure 4a shows the normal lung field of another experimental animal. Ten cubic centimeters of sterile olive oil were injected intravenously and 48 hours later another checkup plate was taken, Figure 4b. The same diffuse cloudiness of both lung fields, so characteristically found in all the experiments, was likewise present. The upper lobes show the pathological condition clearly.

From 2 to 12 cubic centimeters of oleic acid were used in the first 6 animals, while from 2 to 20 cubic centimeters of olive oil were used in the last 5.

The animals receiving less than the lethal doses of oleic acid, 4 cubic centimeters, showed evidence of pulmonary irritation for several days. All of these animals had apparent colds, sniffing and coughing periodically, otherwise they appeared normal.

The animals receiving up to 20 cubic centimeters of sterile olive oil showed no evidence whatsoever of any pulmonary irritation or malaise and had no apparent ill effects from the experiments. One of the animals, after having received 20 cubic centimeters of olive oil, became ataxic and had great difficulty in controlling the extremities, although otherwise it appeared normal. The inebriation

stage lasted about 10 minutes, then he ran around and was normal. This period probably existed while the fat droplets were interfering with the cranial circulation.

One must not lose sight of the fact that fat embolism is not a true embolism in the sense of a permanent occlusion of a vessel, but simply a retardation of the blood flow through a capillary while the oil droplets become elongated and are slowly forced from the arterial to the venous side of the circulation.

THE SIZZLE TEST FOR FAT IN THE URINE

Accidentally in using the platinum loop for the taking of microscopic specimens, the author noted that whenever fat droplets were present, a sizzling and popping occurred when the loop was heated over an open flame. When no sizzling and popping occurred, only rarely were fat droplets ever found in the microscopic examinations.

This observation was investigated further in order to determine the accuracy of this method for fat determinations.

One drop of olive oil was thoroughly emulsified into increasing dilutions of water and the sizzle test tried. The test was very definite until the dilution reached 1 drop to 80 cubic centimeters of water after which the sizzling and popping was not constant. This represented a dilution of 1:400 to 1:1600.

Dilutions of 1 drop in 80 to 120 cubic centimeters gave an occasional pop with a discoloration of the flame. One drop in 130 to 150 cubic centimeters just gave a discoloration of the flame this, of course, was of no value.

A bacteriologist has since informed me that she uses this method for hurriedly finding out whether or not any diphtheria organisms are present in a smear because if they are the heating ignites the fatty capsule producing a characteristic popping. Of course she always checked this observation with a culture.

Normal human and dog urines were tested and found to be approximately the same as the tests run with plain water. When no fat was added, only a yellowish blue discoloration of the flame took place.

This simple test requires no special training, no equipment, and its efficiency makes it almost as accurate as a microscopic examination.

THE TECHNIQUE OF SUDAN III STAINING OF URINE AND BLOOD SPECIMENS

The staining of urine and blood specimens with Sudan III for examination turned out to be a stumbling block in many of the observations because a number of the details which were important were not appreciated. Until many control studies were undertaken to determine the exact technique, many experiments had to be repeated. The conclusions were as follows: (1) The stain must be fresh (2) a high concentration of the dye is necessary to stain the fat droplets (3) the stain must be permitted to act on the fat for at least 5 minutes in order to stain it well (4) orange droplets less than 3 to 4 microns in diameter are either contamination or undissolved stain (5) a drop of stain must be added directly to the slide and not to a test tube specimen.

GARDINOL AND DECHOLIN SODIUM AS THERAPEUTIC AGENTS

Gardinol (sodium lauryl alcohol sulphonate) made by DuPont, is probably one of the most efficient emulsifiers known. A few drops added to an oily mixture produces a very fine and relatively stable emulsion with but little agitation. A study of its value in diagnosis has been described elsewhere.

From previous experiments it was found that 2.2 cubic centimeters of olive oil per kilogram body weight was the minimal lethal dose in dogs. Two animals of about the same size were chosen, weighing 10.1 kilograms and 8.9 kilograms. Both received a lethal dose of intravenous olive oil, 2.2 cubic centimeters per kilogram body weight. Five minutes later when the dogs were very dyspneic, one received 20 cubic centimeters of 2 per cent gardinol and almost immediately the dyspnea subsided but within 10 minutes it had returned to almost the same degree. Twenty cubic centimeters more of 2 per cent gardinol was given but the animal was still very ill. The second animal which had received only the olive oil was in *extremis*. Both were observed for 1 hour the gardinol treated animal being in much better physical condition however it was still very ill. The next morning both were found dead. The un-

treated dog was in *rigor mortis* while the gardinol treated animal was still limp

Postmortem examination of both animals revealed a bloody, frothy exudate in both lungs with patches of massive consolidation, more so in the untreated animal. The kidneys, liver, spleen, and intestine showed diffuse areas of hemorrhagic mottling throughout the organs. Specimens were taken and studied microscopically. Massive occlusion of the vessels with droplets of fat was visible in all the sections.

Six more dogs were injected with 2.2 cubic centimeters of olive oil per kilogram and each received 20 cubic centimeters of 2 per cent gardinol immediately after the olive oil was given, and 10 minutes later. All animals died within 12 hours.

In vitro, this quantity of gardinol, if properly mixed with 20 to 30 cubic centimeters of olive oil, would produce a very fine and durable emulsion. There is no doubt in the mind of the author that some reaction occurs in the body to prevent the same mechanism *in vivo*.

Since bile salts are emulsifiers and saponifiers of fat, many experimenters have entertained the idea that the injection of a bile salt, provided that it was not very toxic, should help to break up the occluding fat, thereby clearing the obstructed vessels of the interfering fat droplets. Until the commercial preparation of decholin sodium was offered, the bile salts were too toxic to be of any real value. Decholin sodium (sodium dehydrocholate) has been recommended by Paul deHaen Chemical Company as a therapeutic agent in the treatment of fat embolism. It is made by the addition of sodium hydroxide to dehydrocholic acid. This was first synthesized by Hammerstein in 1881. This preparation is the least toxic of the bile salts. Rappert did some experimental work with it and recommended it most highly both as a therapeutic and diagnostic agent. In repeating his work I have unfortunately been unable to corroborate his findings.

As has been stated elsewhere 2.2 cubic centimeters of olive oil per kilogram body weight is the minimal lethal dose in dogs if given intravenously. Varying doses of decholin sodium were employed before, during, and after

the lethal quantity of olive oil. In no instance were any of the animals saved. As far as the author is concerned, decholin sodium is of no value in the therapy of fat embolism.

THE MECHANISM OF FAT EXCRETION THROUGH THE KIDNEYS

The author has been unable to find any reference to previous work done on the mechanism of fat excretion through the kidneys. Numerous cases of chylemia have been reported, but all have been purely clinical in their presentation.

This problem was undertaken because of its relationship to the diagnosis of fat embolism in traumatic cases. Before approaching the problem it was necessary to determine whether or not normal dogs under varied physiological conditions ever excreted fat in the urine.

The urine of two normal dogs was examined and found to be negative for fat by microscopic tests described later. Two dogs which had been given one pint of cream, one 3 and the other 6 hours previous to the urine examination, had no fat in the urine. Two other dogs which were being starved in other experiments also showed negative results. The kidneys of these 6 animals were sectioned and stained with Sudan III. In none was there any evidence of fat droplets in either the glomeruli or tubules.

Knowing that dogs under varied physiological conditions did not excrete fat in the urine, its presence should be considered abnormal.

All the animals in the following experiments were operated upon under nembutal anesthesia.

The pedicle of one kidney was isolated through a loin incision and the renal artery carefully dissected from the surrounding tissues. The ureter was then traced to the bladder and cut free, the end being cannulized with a glass cannula. The cannula was then brought out through the anterior abdominal wall through a stab wound and fixed in place. With a very fine needle the fat was injected into the renal artery. When the injection was completed, the renal artery had to be carefully clamped in the longitudinal axis to pre-

vent loss of blood through the needle hole and still not completely occlude the renal artery. Occlusion of the artery would obviously result in cessation of the urinary flow from the isolated kidney. A miniature paper clip was used for this purpose, having a small spring in it. After the fat had been injected the kidney was placed back in the loin and the wound sutured.

Both dog bone marrow fat and olive oil were used in various physical forms. Olive oil or bone marrow fat was used in some emulsified fat in others. As emulsifiers, plain water with a little soap and also solutions of gardinol were tried. The results were uniformly the same. In order to increase the urinary output, intravenous Ringer's solution from 200 to 300 cubic centimeters with 1 gram of caffeine or 200 to 250 cubic centimeters of 2 per cent urea in physiological salt solution were given intravenously. The urine was collected from the cannula in the anterior abdominal wall and examined by centrifuging it for 15 minutes at high speed then staining the supernatant liquid with Sudan III. A film from the surface of the urine was examined under the microscope for the orange colored spherical droplets of fat. When present these varied in size from 3 to 8 microns in diameter.

Results of experiments on a series of dogs and Louisiana bull frogs showed that the intravascular fat is excreted through the kidneys providing that 0.75 cubic centimeters or more fat per kilogram body weight is injected. The fat is excreted not through the glomeruli but only through the tubules. These experiments have been described by the author in detail in a recent article (43).

STUDIES ON THE SURFACE TENSION OF BLOOD SERUM

In the search for methods of accurately diagnosing fat embolism the effect of the fat droplets on the blood serum was studied. It is a well known fact that the mixture of liquids of different specific gravity or the addition of inert particles to a liquid, produces definite changes in the surface tension. With this thought in mind experiments both *in vitro* and *in vivo* were conducted.

In order to eliminate the most common factors that produce errors, the eye glass and the platinum loop of the DuNouy tensiometer were washed first with soap and water followed by ether. They were never used until thoroughly dried.

The average of ten determinations was computed and found to be as follows: Control studies at room temperature—water 85.8 dynes human serum, 90.5 dynes dog serum, 90.4 dynes.

Dogs were subjected to increasing doses of olive oil given intravenously. After a few minutes venous blood was withdrawn from the opposite leg and the blood serum collected by centrifuging the specimen.

Two of the experiments were as follows:
Experiment 6 Normal blood serum reading of this dog was 90.4 dynes. One cubic centimeter of olive oil per kilogram body weight was injected, a total of 6.6 cubic centimeters being used. Reading after olive oil was 90.7 dynes.

Experiment 7 Normal blood serum reading of this dog was 88.5 dynes. One cubic centimeter of olive oil per kilogram body weight was injected, a total of 8.63 cubic centimeters being given. Reading after olive oil was 86.6 dynes.

One cubic centimeter of olive oil per kilogram body weight is about one half the lethal dosage in man a comparable amount would be 70 to 75 cubic centimeters. These two determinations showed but little difference in the readings. Other experiments running up to a lethal dosage (2 cubic centimeters of olive oil per kilogram body weight) showed very little change in the surface tension determinations. Probably many of the olive oil droplets were being held back by the small capillaries of the body and for that reason many of the droplets were not to be found in the general blood stream as we had anticipated.

Further studies were made on the variables produced by olive oil in blood serums *in vitro*. The results were as follows: ratio 151 cubic centimeters per 5000 cubic centimeters of blood—(lethal dose in man) 82.75 dynes ratio 224 cubic centimeters per 5000 cubic centimeters of blood—77.75 dynes.

Fig 2 a, left, Normal lung field, b, 20 minutes after injection of 6 cubic centimeters of oleic acid

Provided that the temperature remained constant and that the specimen did not stand too long, the difference *in vitro* did show an appreciable change provided that larger quantities of olive oil were used

The fact that the surface tension determinations varied with variations of temperature and standing of the specimen only occurred to the author after a number of confusing determinations on the same specimen during the same day. This aspect of the problem was easily gone into and was readily solved. The findings were as follows

VARIABLES PRODUCED BY STANDING

specimen	Surface tension	After 20 minutes standing
No 10	78.25 dynes	80.5 dynes
No 11	78.35 dynes	81.5 dynes

The variation produced by standing alone would be enough to counteract any possible

accuracy of the method. A far more interesting variation was observed with temperature changes. Variations of about 35 degrees of temperature produced around 8 dynes variation in the surface tension. The results were as follows

TEMPERATURE CHANGES USING SAME SERUM

	Degrees C	Dynes
Serum No 3 (without oil)	21.8	88.75
	38.0	86.0
	49.0	83.5
	55.0	81
Serum No 4	21.8	88
	36.5	84
	46.0	83
	57.0	80

These short experiments showed that the numerous variables are too great to be of any real diagnostic value even if the *in vivo* experiments were as promising as the *in vitro* ones

Fig. 3. a, left, Prior to experimentation. b, 5 hours after injection of 1 cubic centimeters of sterile oleic acid.

FAT TOLERANCE IN DOGS—
EXPERIMENTS IN IMMUNIZATION

That animals can be made tolerant to lethal doses of intravenous fat was first shown by Paul and Windholz in 1925. This was later confirmed by Domanig in 1932.

Paul and Windholz used repeated small doses of fat in daily injections. At each injection larger quantities were given. They at first thought that this increased tolerance was due to a greater production of serum lipase. However, careful investigation with the Traube stalagmometer failed to show any such rise. They then concluded that this increased tolerance was due to the acceleration of absorption of the fat by the tissues.

Domanig gave hourly injections of intravenous fat and was also able to create an apparent relative immunity to increasing doses of intravascular fat. He was unable to show any transferable fat dissolving or lipolytic substance created in these animals. He likewise concluded that the increasing doses created an accustomizing reaction of the body to the fat. By careful stool and urine examinations, he showed conclusively that there was no increased elimination which might explain the increased fat tolerance.

The above experimenters used small divided doses given at frequent intervals. The thought occurred to me to give massive sublethal doses with a longer interval between doses in the hope that by using this procedure perhaps the mechanism of fat tolerance might be different.

Paul and Windholz, and Domanig used both olive oil and human bone marrow fat. It appeared to me that if we expect any definite serological reaction, the bone marrow fat from dogs alone should be used in dogs. For this reason bone marrow fat obtained by extracting cut dog bones was used.

It was found that the minimal lethal dose was from 2.2 to 2.5 cubic centimeters per kilogram body weight of the animal.

By weekly injections of increasing doses 4 animals reached a figure of 5 cubic centimeters or more per kilogram body weight before the quantity of fat produced death. One animal received 5 cubic centimeters per kilogram, one 5.5 cubic centimeters, and 2 animals received 6 cubic centimeters per kilogram.

Three dogs were transfused with 65 to 85 cubic centimeters of citrated blood from the animals which had survived 5.5 cubic centimeters of bone marrow fat per kilogram of body weight.

In each instance after the termination of the transfusion, 3 cubic centimeters of dog bone marrow fat were injected per kilogram body weight (a lethal quantity). None of these animals survived. At least for the time being no transferable substance has been found which could be used to transmit a partial immunity or increased fat tolerance from one animal to another. Perhaps none exists and on the other hand perhaps other methods of approaching the problem may isolate it.

CONCLUSIONS

1 The literature shows conclusively that the postmortem table, unfortunately, is not the last court of appeal for fat embolism following fractures.

2 Quantitative blood fat determinations are of no value in the diagnosis, because the physiological variations are too great.

3 Qualitative dark field examinations of the blood should be of great aid in the diagnosis, in the hands of trained microscopists.

4 In the urine examination of suspected cases, only the last few cubic centimeters of a catheterized specimen are valuable.

5 Our uniformity of experimental results makes the author feel that intravenous fat droplets, if present in sufficient quantity, will always produce changes in the lung fields, detectable by the x-ray.

6 The sizzle test, using a platinum loop and a Bunsen burner, is accurate in 1:1400 to 1:1600 dilution. It is very simple and requires no special apparatus nor any complicated equipment.

7 The technique of Sudan III staining of the urine and blood specimens, in order to be accurate, must be done according to the following rules: (a) The stain must be fresh, (b) a high concentration of the dye is necessary to stain the fat droplets, (c) the stain must be permitted to act on the fat for at least 5 minutes in order to stain it well, (d) orange droplets less than 3 to 4 microns are either contamination or undissolved stain,

(e) a drop of stain must be added directly to the slide and not to a test tube specimen.

8. Cardinal and decholin sodium are of no value either as diagnostic or therapeutic drugs.

9. Fat droplets are excreted exclusively through the tubules of the kidney. If the concentration of the fat reaches 0.75 cubic centimeters or more per kilogram body weight.

10. Surface tension studies of the blood serum are of no value in this disease because the variables are too numerous to be satisfactorily controlled.

11. Since all the bone marrow fat extracted from a femur is not sufficient to cause death, the author believes from experimental evidence that oleic acid which is one of the split products of the neutral olein of bone marrow is the probable etiological factor. This substance is seven times as lethal as neutral bone marrow fat, and sufficient quantity could easily be available.

12. Experimentally animals can be made resistant to lethal doses of intravascular fat provided the injections are given in gradually increasing doses. The mechanism of this phenomenon is not clear. Whether it is due to an increased tissue resistance or the formation of an emulsifying agent will require further work.

EXPERIENCES WITH INTRAMEDULLARY TRACTOTOMY

IV Surgery of the Brain Stem and Its Operative Complications

FRANCIS C GRANT, M D, F A C S, and LAURENCE M WEINBERGER, M D,
Philadelphia, Pennsylvania

SURGICAL procedures upon the various extramedullary segments of the trigeminal nerve for the relief of major trigeminal neuralgia or for intractable facial pain due to other reasons have suffered from several drawbacks. All of these have not been eliminated by either the Frazier-Spiller retrogasserian neurectomy or by the Dandy-Olivecrona method of sectioning the trigeminal root in the posterior fossa. In both of these operations the resulting corneal insensitivity permits the occurrence of neuroparalytic keratitis. The face feels numb and stiff and roughly 5 per cent of patients develop distressing dysesthesias which often cause more suffering than did the original neuralgia.

To avoid these complications, Sjoqvist (6) in 1938 proposed cutting the descending tract of the trigeminal nerve within the medulla oblongata. The rationale for this new method was based on the peculiar anatomy of the intramedullary pathways of the trigeminal nerve. A brief and simple description of the central trigeminal fibers will provide the theoretical background of the operation.

The sensory root of the trigeminal nerve enters the brain stem at the junction of the pons and medulla. Immediately upon the entry the fibers undergo an anatomical separation and a physiological dissociation. The fibers mediating touch sensation turn rostrally and enter the main sensory nucleus of the trigeminal nerve and thence by the secondary neuron ascend to the sensory nucleus of the thalamus. The fibers mediating pain sensation, on the other hand, turn caudally and in company with the spinal nucleus of the trigeminal nerve run throughout the length of the medulla and into the upper cervical spinal cord. In the closed portion of the medulla they lie on the superficial lateral aspect where

they form a distinct elevation, the tuberculum cinereum. The tuberculum cinereum is, in this situation, above the olivary eminence and below the restiform body. An incision into the tuberculum cinereum, therefore, cuts the descending tract of the trigeminal nerve and presumably avoids the important nuclei, tracts, and respiratory mechanisms in this neighborhood.

Since only the pain fibers are interrupted, certain advantages are apparent. Touch sensation is spared, and the face does not feel cold and numb. Neuroparalytic keratitis should not result since some sensation is retained in the eye. The motor component is also spared which makes the operation suitable for bilateral trigeminal neuralgia. Furthermore, Sjoqvist believed that facial dysesthesias would not follow this procedure.

Thirty-five operations of this type have been reported, of which 19 cases have been done in this clinic. Nine patients were originally operated upon by Sjoqvist (7), 3 cases have been reported by Rowbottom, 1 by Jackson and Ironside, 2 by Walker, and 1 by Smyth. The results in 19 cases in terms of relief of facial pain have been reported by Grant and Weinberger (3) as well as an analysis of the sensory phenomena (10), and neurologic sequelae (11).

SURGICAL TECHNIQUE AND PLACEMENT OF THE MEDULLARY INCISION

Before Sjoqvist performed this operation for the first time, it was thought extremely hazardous to incise the brain stem. As a matter of fact, it was believed that death could ensue if the medulla was accidentally penetrated during the performance of a cisternal puncture. From experiences with intramedullary tractotomy, it is now known that relatively large incisions may be made in the medulla with small risk to life, if carefully placed.

From the Neurosurgical Service and Neuropathological Laboratory of the Hospital of the University of Pennsylvania.

Anesthesia The premedication used consists of 3 grains of nembutal given at midnight. The morning of operation morphine sulphate grains 1/6 and scopolamine grains 1/150, are given 2-4 hours before operation and again 2 hours before operation. In most instances avertin, 60 to 70 milligrams per kilogram has been used as anesthetic, although in a few cases the premedication was so successful that it was possible to perform the operation with local infiltration of novocain into the scalp. There is an objection to local anesthesia because cutting the tract is painful and the patients move during the section. This can be dangerous since the movement may deflect the operator's hand while the knife blade is in the medulla.

Operative exposure A conventional suboccipital hemiradical craniectomy is performed. It is not necessary to expose the lateral sinus. It adds to the ease of the subsequent manipulations to rongeur the bone a little past the midline. The entire posterior rim of the foramen magnum must be removed. This is especially important on the side of the projected incision since an adequate lateral view of the medulla is the *sine qua non* of the exposure. In taking away the most lateral bit of the foraminal rim, care must be taken not to injure the vertebral artery which enters the cranial cavity about a centimeter below. Although Sjöqvist, in his operative description, did not mention removing the arch of the atlas we have found that a wider and better view of the medulla is secured by so doing. The dura is opened by radial incisions, and the flaps are tacked to the adjacent muscle. A linear incision is then extended downward to open the dura over the upper cervical cord. The arachnoid membrane of the cisterna magna is torn and the cerebrospinal fluid is allowed to escape. The medulla, with the emerging lower cranial nerve roots, comes into view. In most cases a large looping artery, the posterior inferior cerebellar is seen lying against the side of the medulla just under the cerebellar tonsil. The cerebellar tonsil is gently retracted upward and rostrally by a small spatula protected with moist cotton. There are often small arachnoidal adhesions between the tonsil and the medulla, which may be gently separated without trouble. Oc-

asionally these contain small veins which may be coagulated and cut. The tonsil is retracted until the obex of the fourth ventricle is visualized on the dorsal aspect of the medulla and the emerging rootlets of the ninth and tenth cranial nerves are seen on the lateral aspect (Fig. 1).

Placement of the incision and the anatomical problems involved According to Sjöqvist an anatomical landmark selected to indicate placement of the incision is the lowermost rootlet of the vagus nerve. At this level the point of the knife is inserted into the medulla just dorsal to the rootlet and carried dorsally for 4 millimeters. The depth of the incision is 3.5 to 4 millimeters. This incision severs the descending tract and spinal nucleus of the vagus nerve. However if one studies a number of specimens of the medulla, one is struck by the variations in the number of vagal rootlets and their points of emergence from the medulla. It is this fact which most likely accounts for the several different and contradictory directions that Sjöqvist gives in his description of the site of the medullary incision. For instance he writes (7 p. 98) "The incision is situated immediately caudal to the lowermost vagal filaments and a few millimeters dorsal to them. At this point the descending tract is no more covered by the restiform body. The level corresponds to a border between the middle and inferior 2/3 of the eminentia vermis. This corresponds to a level 8 to 10 mm. cranially to the inferior end of the fourth ventricle."

On measuring out these distances on several specimens of the medulla, it was found that a distance of 8 to 10 millimeters above the obex actually corresponded to a level passing through the rostral tip of the olive or in some cases slightly above it. In a number of medullas the lowermost vagal rootlet was at level of the midportion of the olive but not as far rostrally as 10 millimeters above the level of the obex. To add to the confusion the author's drawing which illustrates the site of the incision shows it placed about 2 millimeters above the highest vagal rootlet. Furthermore in case protocol 2 the incision was made 10-12 mm. cranially to the inferior edge of the fourth ventricle. In Case 4 the incision

was made 8 millimeters above the level of the obex while in the 7 other cases it was variously described as being placed at the level of the middle or lower third of the olive or at the level of the lowest vagal rootlet. While Sjöqvist states that the restiform body is avoided by an incision at his recommended level (8 to 10 millimeters above the obex) the cross sectional view of the medulla in which he illustrates the extent of the proposed incision (7) shows the lower half of the restiform body included in the transection (Fig 2a)

It is our belief, from experiences with the operation, that the placing of the incision 8 to 10 millimeters above the level of the obex will result in severe or disabling neurological sequelae in a high percentage of cases. These will come from injury to the restiform body or the main and/or lateral cuneate nuclei which are easily exposed to injury at this level. As in cordotomy, the site and extent of the operation must be measured in terms of millimeters and an error of a millimeter or so at this high level in the medulla may result in disastrous consequences. Although Sjöqvist denies that neurological complications occur, except for an occasional paralysis of the recurrent laryngeal nerve due to handling of the vagal rootlets, his case protocols offer evidence to the contrary. In Case 4 the patient following operation felt

Fig 1 Operative photograph of the medulla oblongata. The tonsil of the cerebellum is retracted to expose the lower portion of the fourth ventricle. The incision, which is marked by a black thread placed in it, is located at a level about 4 millimeters caudal to the obex. Only the dorsal half of the incision is seen, the lower half is concealed by the lateral curve of the medulla. This photograph was taken of Case 2.

numbness in his contralateral extremities and in Case 9 the patient's gait was, "more markedly staggering than on admission." One also gets the impression that neurological compli-

Fig 2 a, left, reproduced from Sjöqvist's monograph (7, Fig 32). The extent of the proposed incision indicated by the shaded area involves almost the lower half of the corpus restiforme, *Cr*. The cross section represents a level at about the middle of the fourth ventricle. b, is a cross section through the medulla taken 4 to 5 millimeters below

the obex and about 2 millimeters caudal to the olive. The extent of the modified incision is shown by the shaded area. At this level the descending tract of the fifth nerve, *Tr V*, is most superficial and covered only by a thin band of external arcuate fibers, *EAF*. The spinal nucleus of the fifth nerve, *Nu V*, is also fairly superficial.

Fig. 3. Diagrammatic representation of the fiber tracts in the medulla. Indicates the site of the incision advocated by Sjöqvist. As shown it transects large bundles of fibers running (1) form the restiform body as well as the underlying cuneate nucleus. Indicates the site of the modified incision. (2) This latter place the incision only severs a few of the dorsal column fibers and entirely spares the restiform body. (Adapted from Figure 613, Gray's Anatomy, edited by Lewis, 9th J. B. Lippincott Co.)

cations may not have occurred in other cases because the incision was not made deep enough to sever the descending tract. This is inferred because in Cases 6 and 7 no sensory alterations resulted in the face and in Cases 1, 2, 3, 5, and 8 complete analgesia was not produced in all three divisions but only in one or possibly two divisions. In 1 of Rowbottom's cases in which Sjöqvist's description was apparently followed the author states that the patient had a mild ataxia of the arm following operation. In a case reported by Smyth and operated upon by Jackson the patient had postoperative incoordination of the arm and a staggering gait.

Since we have had mishaps of this nature an attempt was made based on a review of the known topographical anatomy of the medulla and the relationship of superficial to deep structures, so to modify the site of the incision as to render serious neurological complications unlikely and at the same time to secure an

Fig. 4. Prepared specimen of the medulla oblongata. The stippled band outlines the medullary portion of the tuberculum cinereum which contains the descending tract and spinal nucleus of the trigeminal nerve. The (1) encircles the obex of the fourth ventricle which is the primary landmark for locating the medullary incision. Four to 5 millimeters caudal to it the incision is placed into the tuberculum cinereum as indicated by a dashed line. The incision recommended by Sjöqvist is indicated by a solid line. The latter slit almost inevitably involves the restiform body.

adequate facial analgesia. The following anatomical data are presented to explain the rationale of the modification.

The trigeminal nerve enters the lower portion of the pons and penetrates 4 or 5 millimeters until it reaches the lateral portion of the tegmentum. At this point 4 to 5 millimeters beneath the surface of the brain stem and under cover of the middle peduncle it breaks up into the ascending fibers and into the descending fibers which form the descending tract. As the descending tract courses caudally it becomes more superficial and at the level of the middle of the fourth ventricle it is covered only by the restiform body on the dorsal and dorsolateral aspects. It is at this level that Sjöqvist recommends that the tract be sectioned. As the tract descends still more caudally it emerges from under the restiform body and at the level of the obex it is almost on the surface of the medulla and forms a well defined eminence, the tuberculum cinereum. Four to five millimeters below the level of the obex the restiform body is no longer present and the tract is covered laterally by only the external arcuate fibers and the dorsospino-cerebellar fibers. These run in a vertical ventrodorsal or in a vertically oblique direction so that the incision parallels their course (Fig. 3).

An incision into the medulla at this level cannot injure the restiform body or the cuneate nuclei and can only injure a few external arcuate and dorsal spinocerebellar fibers (Fig 4). A transection at this level 3 to 4 millimeters deep will encompass all the fibers of the trigeminal tract and will assure an adequate facial analgesia (Fig 2b).

It has been thought that only the fibers from the ophthalmic division descend to the cervical cord and that the fibers from the maxillary division end about the level of the lowest glossopharyngeal rootlets. The mandibular fibers were thought to terminate still higher in the medullary portion of the spinal nucleus (8). In 1 case in which we made the incision into the medulla about 8 millimeters below the level of the obex, a total and lasting analgesia was obtained in all three divisions of the face. This experience serves to prove that all divisions of the face are represented in the tract as low as the level of the upper pyramidal decussation. We feel, therefore, that it is safer to cut the medulla more caudally for the descending tract is most superficial and there are no vulnerable structures to be injured by an incision 3 to 4 millimeters deep.

When we first started to perform these operations 2 years ago, we used the level recommended by Sjöqvist (8 to 10 millimeters above the obex). Severe neurological symptoms followed operation which were first partly ignored since it was thought that they were only transitory. As the cases were followed over a period of many months it became evident that in a number of instances the disturbances persisted and produced considerable disability. It was this experience combined with the opportunity to study several postmortem specimens that caused us to modify the procedure. In order to illustrate the possibilities of injury to the restiform body and cuneate nuclei when making the high incision recommended by Sjöqvist, the following case is cited.

CASE 1 R. J. Surgical 43547. The patient was a 46 year old male with carcinoma of the tongue and severe intractable pain in the left mandible. In order to relieve his pain it was thought necessary to render his face analgetic as well as to section the ninth nerve and the upper posterior cervical roots. On March 12, 1939, a suboccipital hemicraniectomy was performed, and the arch of the atlas was removed. The upper

three cervical roots on the left side were cut and the glossopharyngeal nerve was sectioned. The tuberculum cinereum was then visualized by retracting the cerebellar tonsil. An incision was made into the tuberculum cinereum at a level 6 millimeters above the obex and approximately dorsal to the lowest vagal rootlet. The incision was 4 millimeters long and 3 to 4 millimeters deep.

Postoperative course. The patient was examined the day after operation. There was the anticipated analgesia involving all three divisions of the trigeminal territory. Touch sensation was grossly intact. The analgesia also involved the distribution of the upper three cervical roots. His pain had disappeared. However, there was a marked weakness of the homolateral arm and the patient complained of numbness and tingling in the fingers of the homolateral hand, i.e., homolateral to the side of the incision. There was a mild inco-ordination of the arm. The fingers were so clumsy that he could not hold or handle objects. Postural sensation was seriously impaired in the fingers of the left hand, less so at the wrist and slightly at the elbow. There were pseudoathetoid movements of the extended fingers. There was a mild inco-ordination of the left leg. Eight days later the inco-ordination of the arm was still marked though less than after operation. Postural sensation was still impaired in the hand and it still felt numb and tingling. He was unable to stand unsupported because of ataxia and staggering. He fell to the left. The difficulties in gait and equilibrium were disproportionate to the static cerebellar disturbances in the left leg. When discharged at the end of 2 weeks he was still too ataxic to walk unsupported and there was still inco-ordination in the arm and leg. Two months later and just before his death his wife wrote us that he could not walk because of staggering, that his left hand was still clumsy and that it felt numb.

Perhaps had he lived longer many of his neurological disabilities would have improved because our experience shows that this does occur. The operation, however, disabled him for 2 months. In this particular patient the neurological sequelae were a cheap price to pay for the relief of pain but this case emphasizes the serious complications that may occur with high placed incisions. Undoubtedly the restiform body and cuneate nuclei were injured. Although the neurological sequelae tend to disappear in time, 2 to 4 months' disability is a more serious consideration when dealing with cases of trigeminal neuralgia. Most of the patients operated upon in whom the Sjöqvist incision was used had considerable postoperative neurological disturbances. We have now performed 4 operations in which the incision was placed in the tuberculum cinereum 4 to 5 milli-

Fig. 3. Diagrammatic representation of the fiber tracts in the medulla. Indicates the site of the incision advocated by Spöqvist. As shown it transects large bundles of fibers running to form the restiform body as well as the underlying cuneate nucleus. Indicates the site of the modified incision. 1 this latter place the incision only necks free of the dorsal column fibers and entirely obliterates the restiform body. (Adapted from Figure 633, Gray Anatomy, edited by Lewis, 9 & J B Lippincott Co.)

cations may not have occurred in other cases because the incision was not made deep enough to sever the descending tract. This is inferred because in Cases 6 and 7 no sensory alterations resulted in the face and in Cases 1, 2, 3, 5, and 8 complete analgesia was not produced in all three divisions but only in one or possibly two divisions. In Rowbottom's cases in which Spöqvist's description was apparently followed, the author states that the patient had a "wild ataxia" of the arm following operation. In a case reported by Smyth and operated upon by Jackson the patient had postoperative incoordination of the arm and a staggering gait.

Since we have had mishaps of this nature an attempt was made based on a review of the known topographical anatomy of the medulla and the relationship of superficial to deep structures, so to modify the site of the incision as to render serious neurological complications unlikely and at the same time to secure an

Fig. 4. Prepared specimen of the medulla oblongata. The stippled band outlines the medullary portion of the tuberculum cinereum which contains the descending tract and spinal nucleus of the trigeminal nerve. The C-rachis is the obex of the fourth ventricle which is the primary landmark for locating the medullary incision. Four to five millimeters caudad to it the incision is placed into the tuberculum cinereum as indicated by numeral. The incision recommended by Spöqvist is indicated by numeral. This latter site almost inevitably obliterates the restiform body.

adequate facial analgesia. The following anatomical data are presented to explain the rationale of the modification.

The trigeminal nerve enters the lower portion of the pons and penetrates 4 or 5 millimeters until it reaches the lateral portion of the tegmentum. At this point 4 to 5 millimeters beneath the surface of the brain stem and under cover of the middle peduncle it breaks up into the ascending fibers and into the descending fibers which form the descending tract. As the descending tract courses caudadly it becomes more superficial and at the level of the middle of the fourth ventricle it is covered only by the restiform body on the dorsal and dorsolateral aspects. It is at this level that Spöqvist recommends that the tract be sectioned. As the tract descends still more caudadly it emerges from under the restiform body and at the level of the obex it is almost on the surface of the medulla and forms a well defined eminence, the tuberculum cinereum. Four to five millimeters below the level of the obex the restiform body is no longer present, and the tract is covered laterally by only the external arcuate fibers and the dorsospino-cerebellar fibers. These run in a vertical ventrodorsal or in a vertically oblique direction so that the incision parallels their course (Fig. 3).

straight blade to make the incision, we early found that it was difficult, if not impossible, to see the point of the blade enter the medulla. Using a curved blade No. 12 with a sharp point, one has a full view of the knife point and therefore better control over the length and depth of the incision. A bit of wax may be placed on the knife 4 millimeters above the point, to serve as a guard.

NONNEUROLOGICAL COMPLICATIONS

For 1 to 3 days after operation most patients have a marked headache due to blood in the posterior fossa, loss of cerebrospinal fluid, and air in the subarachnoid space. Five patients developed hiccoughs on the second to fifth day. These lasted 3 to 9 days and were refractory to all treatment although carbon dioxide inhalations gave temporary relief. In 2 instances they were very exhausting. No difficulties in swallowing or speech were encountered. In Sjöqvist's series there were 3 instances of recurrent laryngeal paralysis. We have not seen this complication. Although the medulla is necessarily incised in this operation we have not seen any respiratory difficulties on the operating table or thereafter.

MORBIDITY AND MORTALITY

The periods of postoperative hospitalization ranged from 8 to 21 days and averaged 14 days. Two patients with oral carcinoma died from late postoperative pneumonia on the thirteenth and seventeenth postoperative days. At necropsy, one patient showed a widespread pulmonary carcinomatosis and the other multiple pulmonary abscesses. One patient operated upon for a painful carcinoma of the cheek developed a postoperative psychosis which persisted and necessitated his removal to an institution.

SUMMARY AND CONCLUSIONS

The results of the operation in terms of relief of pain have been dealt with in other publications but are briefly summarized in Tables I and II.

Intramedullary tractotomy is neither a difficult nor a complicated operation but requires an intimate knowledge of the topographical and internal anatomy of the medulla oblong-

ata. At present, the procedure is just moving out of the experimental stage. Similar hazards and complications were encountered in the early development of anterior cordotomy and it is expected that apprentice fees must be paid in order to develop, modify, and perfect the technique.

Although we do not, at present, feel that the operation is acceptable as a routine procedure in cases of trigeminal neuralgia, various conditions exist in which it might be considered the operation of choice. In cases of severe trigeminal neuralgia affecting the upper or upper two divisions or all three divisions of the face, tractotomy avoids the possibility of neuroparalytic keratitis which might result from the complete section of the root required to relieve the pain. In cases in which neuralgia has developed on the second side after a previous retrogasserian neurectomy has been performed, tractotomy avoids involvement of the motor component and preserves masseter function. In neurotic persons in whom one might expect severe distress from postoperative numbness if the sensory root were sectioned, tractotomy is indicated since there are fewer unpleasant subjective sensations in the face. Not infrequently careful questioning shows that a patient has a burning pain in the face between the paroxysms of true neuralgia. Our experience with such cases has taught us that this burning pain may persist in the anesthetic area and even be accentuated by the presence of the anesthesia. Medullary tractotomy relieves the paroxysmal pain without producing subjective sensory changes in the face. If the complete anesthesia produced by sensory root section could thus be avoided the burning paresthesia might be much less annoying. It has its widest application in cases of malignant disease about the head where pain makes it desirable to render the face analgetic. Since it is often necessary also to section the ninth nerve and posterior cervical roots, tractotomy can be easily done through the same exposure.

Most of the advantages claimed for the operation have been confirmed in our experience. Touch sensation for all practical purposes is preserved, and the patients are hardly aware that their faces have been made analgetic. No cases of neuroparalytic keratitis have been ob-

meters below the level of the obex. In comparison with the case described we cite one such patient operated upon with the modification in the placement of the incision.

CASE V. E. Surgical 3695. The patient was a 5-year-old woman who had suffered with major trigeminal neuralgia, second and third divisions, for 2 years. She had received temporary relief from alcoholic injections but finally demanded permanent relief. An intramedullary tractotomy was performed April 24, 1940. The obex was used as the landmark and the tuberculum cinereum as transected at level 4 to 5 millimeters below the obex and about millimeters below the olive (Fig. 1).

Postoperative course. Six hours after operation the patient was clear and co-operative. Examination disclosed a slight inco-ordination of the homolateral arm. Her grip was good and there were no subjective sensations in the hand. Postural sensation was intact. By the end of 24 hours the inco-ordination had practically disappeared in the arm. There was complete analgesia in all 3 divisions of the fifth nerve.

With gross preservation of touch sensation. When put on her feet on the third postoperative day she was unable to walk and fell promptly to the right side. Again the disturbances in equilibrium and gait were disproportionate to the static cerebellar signs for there was only the trace of a heel to knee ataxia when tested in bed. By the fifth postoperative day she was able to walk unsupported, although she frequently staggered to the right side. Her gait rapidly improved and by the twelfth postoperative day there was little evidence of disturbance. The Romberg sign was not present. There was no inco-ordination in either of the right extremities. One month after operation she was performing full household duties. Her only neurological complaint was little incoordination in descending steps. Two months after examination she was examined and found to be neurologically normal. Her pain was entirely relieved and there was complete analgesia of the three trigeminal divisions.

While mild neurological disturbances were present after operation they were only tran-

* At least six did not demonstrate decrease of C X II

sient and she left the hospital essentially a normal person. These transient symptoms were probably due to cutting of a few spinocerebellar and arcuate fibers and to the regional edema of the medulla. This case typifies the differences in the postoperative course when the incision is made low in the medulla as compared to the previous case in which it was made higher. Neurological compensation apparently is made readily after injuries to the spinocerebellar tracts and arcuate fibers whereas the defects are more profound and less recoverable when the retiform body or cuneate nuclei are injured. This has been shown experimentally in monkeys by Ferraro and Barrera.

Before ending the section on the surgical and anatomical problems brief mention should be made of several other difficulties encountered in the course of medullary surgery. Occasionally thick congenital small vessels may be clustered over the area selected for the incision. This forces one to make the incision a millimeter or so away. We have adopted the policy of moving the incision caudally the required distance since the descending tract remains superficial throughout the lower medulla. It is unwise to coagulate these vessels on the medulla since the electric current is carried along the vessels into the brain stem and might produce serious results. If the incision is made into an avascular area, hemorrhage never occurs. Although Sjögqvist used a

straight blade to make the incision, we early found that it was difficult, if not impossible, to see the point of the blade enter the medulla. Using a curved blade No. 12 with a sharp point, one has a full view of the knife point and therefore better control over the length and depth of the incision. A bit of wax may be placed on the knife 4 millimeters above the point, to serve as a guard.

One patient operated upon for a painful carcinoma of the cheek developed a postoperative psychosis which persisted and necessitated his removal to an institution.

SUMMARY AND CONCLUSIONS

The results of the operation in terms of relief of pain have been dealt with in other publications but are briefly summarized in Tables I and II.

Intramedullary tractotomy is neither a difficult nor a complicated operation but requires an intimate knowledge of the topographical and internal anatomy of the medulla oblong-

ata. At present, the procedure is just moving out of the experimental stage. Similar hazards and complications were encountered in the early development of anterior cordotomy and it is expected that apprentice fees must be paid in order to develop, modify, and perfect the technique.

Although we do not, at present, feel that the operation is acceptable as a routine procedure in cases of trigeminal neuralgia, various conditions exist in which it might be considered the operation of choice. In cases of severe trigeminal neuralgia affecting the upper or upper two divisions or all three divisions of the face, tractotomy avoids the possibility of neuroparalytic keratitis which might result from the complete section of the root required to relieve the pain. In cases in which neuralgia has developed on the second side after a previous retrogasserian neurotomy has been performed, tractotomy avoids involvement of the motor component and preserves masseter function. In neurotic persons in whom one might expect severe distress from postoperative numbness if the sensory root were sectioned, tractotomy is indicated since there are fewer unpleasant subjective sensations in the face. Not infrequently careful questioning shows that a patient has a burning pain in the face between the paroxysms of true neuralgia. Our experience with such cases has taught us that this burning pain may persist in the anesthetic area and even be accentuated by the presence of the anesthesia. Medullary tractotomy relieves the paroxysmal pain without producing subjective sensory changes in the face. If the complete anesthesia produced by sensory root section could thus be avoided the burning paresthesia might be much less annoying. It has its widest application in cases of malignant disease about the head where pain makes it desirable to render the face analgetic. Since it is often necessary also to section the ninth nerve and posterior cervical roots, tractotomy can be easily done through the same exposure.

Most of the advantages claimed for the operation have been confirmed in our experience. Touch sensation for all practical purposes is preserved, and the patients are hardly aware that their faces have been made analgetic. No cases of neuroparalytic keratitis have been ob-

served nor have we even witnessed reddening of the conjunctiva. In the majority of cases, even with complete analgesia of the ophthalmic division a blink reflex may be elicited. While pain sensation is lost in the cornea and the affective component of corneal irritation is absent, the patients are able to feel a stimulus on the cornea, the sensation being described as a light touch or tickle. Although it is too early to speak with assurance about postoperative dysesthesias we have 4 patients with subjective facial sensations. In no case have they spontaneously complained of these sensations and in no instance have they been of the disagreeable or distressing character as are often a source of distress after sensory root section. One patient had slight burning sensations about the eye which were annoying but perfectly tolerable. One had prickling and tingling sensations for which he rubbed his face with liniment. One woman complained of brief paroxysms of burning at the angle of the mouth, and one stated that he had chilly sensations and the illusion that his nose was watering.

Theoretically there is no reason why interruption of the intramedullary trigeminal pathways should not be followed by dysesthesias. It is well to recall in this connection the fact that thromboses of the posterior inferior cerebellar artery which always involve the descending tract of the trigeminal nerve, are accompanied, in the majority of cases, by severe burning dysesthesias (12). Only a larger

experience will determine whether they occur following surgical transection of the tract.

EXPERIMENTAL CEREBRAL TRAUMA

II — Further Observations on the Fluid Content of the Brain Following Trauma to the Head

COBB PILCHER, M D , F A C S , Nashville, Tennessee

IN experiments previously reported (2), it was found that there was little, if any, significant alteration of the fluid content of various parts of the dog's brain after trauma to the head sufficiently severe to produce a marked rise in cerebrospinal fluid pressure. Since, theoretically, with skull and dura mater intact, an increase in tissue fluid volume could occur only at the expense of a diminution in intracranial blood or cerebrospinal fluid volume, similar experiments have been made with one hemisphere of the brain freely exposed. These experiments offer the additional advantage of comparison of the exposed with the unexposed hemisphere, as well as with normal control values.

METHODS

Anesthesia, position of the head, and methods of sacrifice of the animals and isolation of specimens of cerebral gray and white matter, cerebellar gray matter and brain stem are exactly as described in the previous study (2). Specimens of cerebral gray and white matter were removed from both hemispheres in all experiments. Fluid content was determined by drying to constant weight at 60 degrees C as before. Trauma was administered by dropping a 1000 gram weight from a distance of 60 inches twice in rapid succession. This degree of trauma has been found to produce consistently a marked elevation in cerebrospinal fluid pressure when skull and dura are intact. Cerebrospinal fluid pressure and femoral arterial pressure were determined as in the preceding study.

Two types of experiments were performed. In the first type, the entire left cerebral hemisphere was exposed, the dura being incised in stellate fashion and its flaps laid back. The

exposed brain was lightly covered with a flat sheet of warm, moist cotton which was moistened from time to time with warm physiological saline solution. No trauma was administered. After intervals of from 4 hours to 5½ hours, specimens were rapidly removed for determination of fluid content. Seven such experiments were performed.

In the second type of experiment, trauma was administered as described and the left hemisphere was exposed immediately afterward. The animals were sacrificed and specimens were secured 4 hours after trauma in 2 experiments, 4½ hours after trauma in 2 experiments, and 8 hours after trauma in 2 experiments. No visible hemorrhage was present in any experiment.

RESULTS

Left hemisphere exposed. No trauma. The arterial blood pressure was not significantly altered during any experiment. The cerebrospinal fluid pressure was very slightly elevated in one animal (Dog T 67) and elevated 185 millimeters of water above the control level in another (Dog T 68). In the latter the cotton pad over the left hemisphere was adherent to the brain at the end of the experiment. When it was gently removed, a gush of fluid followed and the cerebrospinal fluid pressure fell to the control level. In the remaining experiments, the cerebrospinal fluid pressure was not altered. Bulging of the exposed hemisphere at the end of the experiments was absent in 5 dogs, slight in 1 dog, and marked in 1 dog.

The fluid content of the brain specimens is given in Table I. Although there were occasional individual variations, the findings, for the most part, were surprisingly uniform as was found in the previous study. No significant difference could be demonstrated between the fluid contents of corresponding specimens

from the left and right hemispheres. Average findings were almost identical in the two hemispheres and they also corresponded very closely with the findings in normal control animals, as will be pointed out later.

Left hemisphere exposed. Severe trauma. The arterial blood pressure showed a transitory fall followed by a slight elevation immediately following trauma. Otherwise it was not significantly altered. The cerebrospinal fluid pressure was not measurably elevated during any of the experiments, doubtless due to the open wound through which fluid could freely pass. The exposed left hemisphere bulged moderately in 4 experiments and not at all in 1. In the single remaining experiment (Dog T 70) the brain was actually shrunken and retracted from the dura by the end of the experiment. In this animal, the respirations rose from a control rate of 30 to 80 per minute 1 hour after trauma, then slowly fell to and remained at, 40. The dog was moderately cyanotic, but the

arterial blood pressure maintained a constant normal level.

The fluid contents of the specimens from the dogs' brains are shown in Table II. The uniformity of the various values is even more striking than in the untraumatized animals. In every experiment, there were almost identical values for corresponding specimens from the two hemispheres, and the average findings are virtually the same as normal control values (see below).

For purposes of comparison a composite table of averages is presented in Table III. The extremely close correspondence of values for the respective specimens in the different groups of experiments is self-evident.

SUMMARY AND CONCLUSION

In an excellent study of traumatized human brains, Shapiro and Jackson have found actually subnormal values for the water content of traumatized brains. Using the iron determination method, they also have shown that the

*Experiments reported in preceding paper (4).

intracerebral blood volume, whether intravascular or extravascular, is greater than normal in such brains (Pilcher, 2) They state, "In the traumatized head the brain is accordingly swollen but not edematous, the swelling is not due to increased water but to increased blood content "

Alexander and Looney studied the brains of a series of patients who died in a psychiatric hospital They concluded that the water content of the brain is not "positively correlated with edema or atrophy of the brain " It is apparent that the contradiction between these two quotations is one of terminology and not of fact The *American Illustrated Medical Dictionary* defines "edema" as "swelling due to an effusion of water liquid into the connective tissue," but Alexander and Looney apparently employ the term to describe brains the size of which is greater than normal They state, "Atrophy or edema of the brain can be meas-

ured quantitatively only by the differential ratio of skull capacity to brain volume or brain weight " The findings of Alexander and Looney do not offer proof of the existence of "cerebral edema," within the meaning of the definition quoted

The experiments reported in this paper clearly demonstrate the marked stability of the fluid content of brain tissue Under these experimental conditions, no significant change in fluid content has been produced

PLASMA PROTHROMBIN VALUES OF MOTHERS AND INFANTS AT DELIVERY

Further Studies Including Comparative Values of the Umbilical Arteries and Veins

ROBERT F. NORRIS, M.D. and MATTHEW C. BENNETT, M.D.
Philadelphia, Pennsylvania

THE widespread interest in prothrombin and vitamin K deficiencies has been responsible for several studies on the relationship of these deficiencies to the hemorrhagic diseases of the newborn. The simple clinical method of Quick (1) and Stanley Brown and Bancroft (16, 17) or one of its modifications (11, 12, 13) and the more complicated two-stage titration method of Warner Brinkhous and Smith (19, 23) have been the favorite procedures for the estimation of prothrombin deficiency and therefore indirectly in certain instances of the vitamin K deficiency. At the time of birth, by the Warner method the blood prothrombin has been shown by Brinkhous, Smith, and Warner (4) by Owen Hoffman, Ziffren, and Smith (9) and by Hellman and Shettles (5) to be only about one-quarter that of the normal adult. By the Quick method, however this deficiency is not so apparent since an increase in the convertibility of prothrombin into thrombin may compensate in part for the deficiency of the former (9). With their method Quick and Grossman (14, 15) found, however that the prothrombin values of the newborn varied between 60 and 70 per cent of normal.

The available evidence also indicates that in many infants a marked fall in the level of prothrombin may occur 2 or 3 days after birth (9, 14, 15, 20, 21). A gradual rise in the prothrombin level during the next week normally occurs, but this change may be accelerated by the oral administration of vitamin K (18). It is during these first days of life, therefore when the plasma prothrombin is low that hemorrhage is apt to occur.

Employing the method of Warner Brinkhous, and Smith (19, 23) Hellman and Shettles (5) were the first to compare the prothrombin levels of mother and infant. They found that the concentration of prothrombin in normal full term infants averaged less than one-quarter that in the mothers. Norris and Rush, using the Quick method, found that in the case of 50 mothers and their babies the average level of the babies was 63 per cent of the normal controls and that of the mothers 140 per cent when 25 per cent diluted plasmas were compared as against 85 per cent and 117 per cent, respectively when undiluted plasmas were compared.

Hellman and Shettles (5) likewise noted that the level of plasma prothrombin tended to be even lower in immature infants than in full term babies. Kato and Poncher (7) however found no correlation between the infant's maturity and the prothrombin level of the blood as measured by the micro-prothrombin method of Kato (6). When the prothrombin level by this method was determined on successive days following birth a greater fluctuation of the values was observed in the blood of the premature than in the mature infants.

The cause of the low prothrombin content in the cord blood of the fetus and the apparent fall in the plasma prothrombin level of many infants after birth has not been determined. Norris and Rush suggested that since the prothrombin concentration of mothers at delivery averaged above normal a deficiency of maternal vitamin K probably is not responsible for the low prothrombin of the fetuses. Since the rôle of the liver in elaborating prothrombin from vitamin K has been established

From the Vascular Laboratory and the Obstetric Service (Philadelphia Lying In) of the Pennsylvania Hospital.

in experimental animals (2, 14, 15, 19, 22, 23), it has been assumed that the liver of the fetus and newborn is likewise responsible for the formation of prothrombin (14, 15). During intra-uterine life, therefore, vitamin K must be supplied to the fetal liver by way of the mother, but after delivery this source of supply is abruptly removed. Quick (14, 15), therefore, believed that this sudden removal of vitamin K is responsible for the fall of plasma prothrombin during the first days of life. Since Almquist and Stokstad have shown that in the intestinal tract of chicks bacteria may synthesize vitamin K, Quick (14, 15) suggested that when the bacterial flora of the infant's intestinal tract is established vitamin K may be produced by bacterial activity in the intestines. The time when vitamin K thus becomes available corresponds to the time when a rise of the prothrombin level normally occurs.

Because of these uncertainties it was thought important to study a large series of cases in order to determine whether any relationship exists between the prothrombin levels of individual mothers and babies. It also seemed advisable to ascertain whether the prothrombin levels of umbilical arteries and veins are identical in individual cases.

METHODS

In the comparison of the individual maternal and infant prothrombin levels, 35 additional cases were added to the original 50 cases of Norris and Rush. All prothrombin values were determined by the method of Quick (16, 17). In the 35 new cases the plasma prothrombin was determined not only in the umbilical vein but also in the umbilical artery. For this purpose blood was collected by the method of Boyd and Wilson. At the time of delivery the umbilical cord was sectioned without clamping 10 to 12 centimeters from the fetus. Blood which ran freely from the placental end of the cord was assumed to be largely from the umbilical vein and blood which spurted from the fetal end was assumed to be from the umbilical artery. Collected simultaneously in separate paraffin-lined beakers, the specimens were immediately mixed in test tubes with the appropriate amounts of sodium oxalate solution. Blood was also col-

lected at once by venipuncture from the mother. In the preparation of the solution of thromboplastin we have followed Quick's modification (11, 12, 13) of his original method in regard to heating the saline mixture and the omission of the oxalate solution from the saline preparation of rabbit brain, but we have continued to use normal hospital workers as controls on each day that determinations were made instead of using Quick's formula for computing the prothrombin values of unknown plasmas. Our experience has been in agreement with Pohle and Stewart's in that the 0.025 molar calcium chloride solution used by Quick often gives slower clotting times than solutions of lower concentration. Consequently, in the last 17 cases we have employed 0.005 molar calcium chloride solution for all determinations. Although the speed of clotting with this concentration is increased the relation between unknown and control appear to be maintained in the same proportion. In all cases we have compared not only the undiluted plasmas of the unknown with the dilution values of the control, but we have also compared the 25 per cent diluted plasmas of each. For interpolation of these dilutions and for the evaluation of an unknown undiluted plasma which clots faster than the control, we have used the formulas of Norris and Rush. In 22 of the last 35 cases the volume of packed erythrocytes in the blood of umbilical artery and vein was also measured.

RESULTS AND COMMENTS

The prothrombin values of 35 additional mothers and babies at delivery were averaged with the 50 mothers and 51 babies (including one pair of identical twins) previously reported by Norris and Rush. Prothrombin determinations on blood from only the umbilical veins of the babies were included in the series. In Table I the average prothrombin value of undiluted maternal blood plasma is seen to be 111 per cent and that of the fetal blood to be 77 per cent of normal. The average prothrombin value, when the plasmas diluted to 25 per cent are compared, is seen to be 136 per cent and 64 per cent, respectively. In the first 50 cases reported a tendency for dilution of the plasmas to increase the value

Chart Undiluted plasmas. Comparison of individual prothrombin values in percentage of normal in 85 mothers and their babies. Solid dots are maternal. Thick curves are fetal values.

of prothrombin in the case of the mothers and to diminish it in the case of the babies as compared to the normal controls was also observed. The explanation for this difference is not apparent, but it has been suggested that dilution of the plasmas may increase the accuracy of the test (8, 9, 14, 15). At any rate the low prothrombin level of infants at birth

does not appear to be caused by vitamin K deficiency in the mothers.

It is of interest that so many of the maternal plasmas appeared to have higher than normal prothrombin values. In the case of the undiluted plasmas 31 were greater than the respective controls and in the 25 per cent diluted plasmas 65 of the 85 maternal plasmas were greater than the controls.

Little has been said in the literature of the possibility that certain individuals may have greater than normal prothrombin values. Poble and Stewart have found that with the Quick test normal plasma will clot in 10 seconds in the presence of an optimal calcium concentration but this time is the minimum unless the plasma is grossly lipemic when slightly faster times may be obtained. Such findings imply at any rate that if clotting is faster than normal the increased speed is not due to more than a normal amount of prothrombin. Even by varying the amount of added calcium in an effort to find the optimal concentration, as suggested by Poble and Stewart we have been unable to obtain for normals minimum clotting time approaching 10 seconds. The clotting time for normal undiluted plasmas, depending upon the solution of thromboplastin used, varies between 12 and 14 seconds in our hands. In a number of cases in which the clotting time of the mother's plasma was faster than that of the normal control varying the calcium concentration did not reduce the clotting time of the normal to that of the mother's plasma. None of these plasmas, furthermore, was lipemic. It appears to us, therefore, that if the increased speed of clotting of many of the maternal plasmas is not due to increased amounts of prothrombin the factors responsible for this phenomenon are as yet undetermined.

Chart 2 Twenty five per cent diluted plasmas. Comparison of individual prothrombin values in percentage of normal in 85 mothers and their babies. Solid dots are maternal values, circles are fetal values.

In Charts 1 and 2 the individual prothrombin values of mothers and babies at delivery in percentage of normal are compared. Chart 1 is a comparison of the undiluted plasmas and Chart 2 of the 25 per cent dilutions. The solid dots are the maternal prothrombin values, arranged in diminishing order of percentage, and the circles are the prothrombin values of blood from the umbilical veins of the respective infants. From these charts it is quite apparent that there is no correlation between the amount of the plasma prothrombin of individual mothers and babies. In the case of the undiluted plasmas in Chart 1 some of the infants even have higher values than their mothers. In Chart 2 none of the infant prothrombin values exceed their mothers' prob-

Chart 3 Percentage differences of prothrombin values between individual umbilical arteries and veins in the case of undiluted and 25 per cent diluted plasmas. Above the zero line are those cases in which the value of the vein exceeded the artery, below the line those in which the artery exceeded the vein, and on the line those in which the artery and vein were equal. Thirty five cases.

ably because of the tendency of dilution to increase the spread in the prothrombin levels of mothers and babies. It may be concluded, therefore, that the amount of plasma prothrombin in the infant at delivery is not directly dependent on the amount of maternal prothrombin.

The prothrombin values in blood from the umbilical artery and vein were compared in the 35 additional cases which we are reporting. In Table II it will be seen that the mean prothrombin value of blood from the umbilical veins exceeds that of the umbilical arteries by 6 per cent in the undiluted plasmas and by 11 per cent in the 25 per cent diluted plasmas. In Chart 3 the differences in veins and arteries of the 35 cases are plotted. Above zero are plotted the differences in percentage of those cases in which the plasma prothrombin is greater in the vein than in the artery and below zero those cases in which the value of the artery is greater than in the vein. On the zero line are those cases in which the plasma prothrombin is identical in artery and vein. It will be seen that in 24 of the 35 cases the value for the vein exceeds the artery. Although these cases are too few and the spread of values is too great for statistical analysis, especially when it is possible that the Quick test is not accurately quantitative, the number of cases in which the plasma prothrombin is higher in

the vein than in the artery is great enough to indicate that similar results might be obtained in a large series of cases. If it is assumed therefore for purposes of discussion that these results are not due solely to chance and are a definite indication of differences in the artery and vein, several possible explanations should be considered.

The first possibility is that absorption of fluid from the fetal circulation through the placenta into the maternal circulation might increase the concentration of prothrombin in the plasma of the umbilical vein. In 22 of the 35 cases the volume of packed erythrocytes was measured. In 3 cases the volumes were identical. In 10 cases the volume was greater in the artery than in the vein and in 9 cases the volume was greater in the vein than in the artery. The usual variation was not greater than 1 per cent. Hemoconcentration therefore is not a significant factor in increasing the concentration of prothrombin in the umbilical veins.

It may be that factors other than prothrombin which influence the speed of clotting are responsible for the apparent differences in the prothrombin values of arteries and veins. Pohle and Stewart have shown that changes in the calcium concentration affect the speed of clotting and there is reason to suppose that changes in the concentration of other electrolytes might have a similar effect. We have no data in the present study on differences in the electrolytes of the umbilical artery and vein. As already indicated Pohle and Stewart found that lipemia will increase the speed of clotting. This observation may have a bearing on the present study since Boyd and Wilson reported that blood in the umbilical vein has a higher lipid content than blood in the umbilical artery. Although determinations of fats and lipoids have not been made in these cases, it may be pointed out that in no instance was the plasma from the umbilical vein grossly lipemic.

In spite of these possible explanations, however, the increase in the amount of prothrombin in the umbilical vein may be not only apparent but also real. No one has suggested that prothrombin itself will pass directly from the maternal into the fetal circulation and the

lack of any relationship between the amount of maternal and fetal prothrombin indicates that diffusion from mother to child is unlikely. If such diffusion does not occur therefore, it is possible that prothrombin may actually be formed by the placenta during the period of gestation and the fall in the prothrombin level of some infants following birth may be due in part to the removal of such a source of supply.

SUMMARY AND CONCLUSIONS

1. By the Quick method the average plasma prothrombin value of 85 mothers at delivery was greater than the normal controls. The average value of their infants was less than the normal controls.

2. No relationship between the level of prothrombin in mother and baby could be demonstrated. It is unlikely therefore that prothrombin passes directly from mother to fetus.

3. A comparison of the plasma prothrombin levels of the umbilical artery and vein in 35 cases showed that in approximately 70 per cent of these cases the prothrombin value of the vein exceeded that of the artery.

4. If this apparent difference between artery and vein is a real one it is possible that prothrombin may be formed by the placenta.

The authors are indebted to Dr. Norma W. Vaut, Clifford B. Lutz, and Robert A. Kimbrough, J. for permission to use their cases, and to Miss Marian M. Janney for her technical assistance.

RESULTS OF PLASTIC OPERATIONS ON THE RENAL PELVIS AND URETER

ABRAHAM HYMAN M.D. F.A.C.S. and SEYMOUR F. WILHELM M.D. F.A.C.S.,
New York, New York

THE answer to the question "Are plastic operations on the renal pelvis and ureter justified?" can be found only in a careful analysis of single case reports with postoperative pyelographic follow-up. The authors, therefore, have studied individually the 32 plastic operations performed at the Mt. Sinai and the Beth Israel Hospitals during the past 3 years. Most of these patients were operated on by the authors, several by the late Dr. Edwin Beer and a few cases by other staff surgeons.

There were 5 operations of necessity the ureter being reimplanted during pyelolithotomy. These cases have been reported in detail elsewhere (7). There were failures in 1 the anastomosis did not heal. The ureter separated from the pelvis and the kidney was subsequently excised. In the second unsuccessful reimplantation the anastomosis healed well. However the stoma was some what narrowed and the kidney which had been grossly infected at the time of operation, gradually became functionless.

These 5 patients, operated on by 5 different surgeons, constitute a special group. In all the kidney was the seat of a calculus with severe infection. The pelvis and ureter were markedly inflamed, and their friability was in every instance considered by the operator the predisposing cause of the avulsion. In 2 of the cases, however the immediate cause was undue traction on a loop around the ureter. The infiltrated condition of the tissues, as well as the irregularity of the tear made accurate approximation impossible. Despite these difficulties, good functional results were observed shortly after operation and at later pyelographic examinations in 3 of the 5 cases of ureteral avulsion.

The 27 remaining plastic operations were done for hydronephrosis caused by obstruction at the ureteropelvic junction. There were 3 patients in whom a plastic was performed on a solitary kidney. One patient, suffering from bilateral obstruction had both sides operated on.

Relief of the obstruction was the primary object of the surgical treatment in all cases. In 12 in

stances, the cause of the blockage was extrinsic, that is, due to vessels, bands, or adhesions, arising from outside the urinary passages. In 13 cases, the obstruction was due to intrinsic lesions, such as stricture or abnormal insertion of the ureter. In the 2 remaining cases, a portion of the redundant pelvis was resected following pyelolithotomy. The authors have excluded from this study all cases of hydronephrosis due to extrinsic obstruction or to calculus, unless plastic operation on the renal pelvis or ureter was also done.

A dilated kidney and pelvis often will return to relatively normal size if the obstruction is relieved at an early stage. This is especially true in calculous cases in which the obstruction is frequently quite sudden. On the other hand, in some of the larger and more chronic hydronephroses, it was deemed necessary in addition to relieving the obstruction, also to reduce the size of the redundant pelvis by resection or plication.

Simpl. resection. Resection of the dilated pelvis was the sole plastic procedure in 13 cases. The ureteropelvic obstruction had been adequately relieved by division of aberrant vessels or adhesions or in 2 instances by pyelolithotomy (Table 1). One patient died of accidental mercury poisoning 8 days after operation. This curiously was the only death in the 32 plastic operations. The obstruction was unrelieved in only 1 of the 10 cases in which patients returned to follow-up; nephrectomy was done. The 9 other patients were followed from 3½ months to 12 years; they were well with good renal function. All but one were controlled by excretory or retrograde pyelography and frequently by both.

One of these cases illustrates the value of preliminary nephrostomy drainage in the treatment of grossly infected obstructive hydronephroses.

CASE 6. Beth Israel Hospital No. 8,402. This 34 year old man, as admitted to the hospital with severe pain in the left loin and high temperature due to purulent hydronephrosis (Fig. 1) A nephrostomy as performed without mobilization of the kidney. The patient's condition improved and 3 weeks later the kidney was exposed and mobilized. The pelvis was still greatly dilated, and there were large aberrant vessels. Its fibrous bands running over and constricting the ureteropelvic junction. The

From the Urological Surgical Services of the Beth Israel and Mt. Sinai Hospitals.

vessels and bands were divided. The pelvis was opened, a calculus was removed, and an oval flap from the redundant posterior pelvic wall was excised. A nephrostomy tube was reinserted and a second splinting catheter was placed in the ureter and brought out through the cortex adjacent to the nephrostomy. An excretory urogram (Fig. 2), made 3 years after operation, showed excellent function and a much smaller pelvis on the side operated on.

Pelvic plication. In 1 case (Beth Israel Hospital No. 104,488) the dilated pelvis was plicated after the obstruction had been adequately relieved by the freeing of ureteropelvic adhesions. A nephropexy was done. A good anatomical and functional result was seen on the excretory urogram 1½ years later.

The pelvis was plicated in 2 other cases, one (Case 31) in association with a side-to-side anastomosis, and the other (Case 27) in addition to section and reimplantation of the ureter. The end result in both of these cases was good. Pelvic plication seems to add little to the risk of operation.

Plastics at the ureteropelvic junction. The obstruction was intrinsic in 13 cases, having been caused either by stricture or by abnormal insertion of the ureter. These cases presented a more difficult surgical problem and were treated by a variety of plastic procedures. They are classified under the following headings: (a) Fenger pyeloplasty (2), Y-plastic (3, 11), (b) section of the ureter with reimplantation into the most dependent portion of the pelvis (8, 9), (c) lateral anastomosis of the ureter to the lowermost portion of the pelvis (1).

Fenger pyeloplasty. Three Fenger pyeloplasties were done, all before 1932. One patient (Mt. Sinai Hospital No. 299,803) was unrelieved and came to nephrectomy 4 years after operation. The second patient (Beth Israel Hospital No. 37,399) suffered several attacks of acute pyelonephritis and later developed a large perinephric abscess which was drained. Subsequently he passed a small calculus. Despite these complications, however, an excretory urogram made almost 3 years after operation showed good function and a smaller pelvis (Figs. 3 and 4). The third case (Mt. Sinai Hospital No. 344,622) also developed perinephritis, but 4 years later showed good function on excretory urography. He still complained of occasional loin pain.

Y-plastic. Two Y-plastic operations were done. In the first case (Beth Israel Hospital No. 105,877) there was little, if any, improvement in renal function despite a satisfactory anatomical result. The parenchyma had obviously been irretrievably damaged by long standing obstruction and infection. A conservative plastic operation was at-

TABLE 1—Results

Avulsion of ureter	Cases	Fol lowed	Success ful	Failed	Deaths
Reimplantation	5	5	3	2	0
Hydronephrosis Plastic operations					
Simple resection	13	11	9	1	1

tempted in this case only because the function of the other kidney had also been impaired by adhesions causing ureteropelvic obstruction.¹ In the second case (Beth Israel Hospital No. 116,482) an excretory urogram, made 7 months after operation showed excellent renal function and a small pelvis.²

Results. The published results of the Fenger operations have been, for the most part, poor (4, 5). Animal experiments indicate that the obstruction is often unrelieved due to buckling of the posterior ureteral wall opposite the plastic suture line. On the other hand, the satisfactory anatomical and functional results in 2 of our cases proves that this is not a constant occurrence. In both of these cases, however, the patients were later operated on for perinephritis. It is interesting to speculate whether the failure to provide free urinary drainage by nephrostomy may have contributed to the high incidence of postoperative perinephric infection.

The Y-plastic, a modification designed to overcome the objections to the Fenger pyeloplasty, resulted in an apparently adequate stoma in our 2 cases. The functional result in one was poor, however, the parenchyma having been irretrievably damaged.

Section and reimplantation of the ureter. The authors have observed 6 cases in which the ureter was completely severed and then reimplanted into the dependent portion of the pelvis. These cases were followed for a period of from 1½ to 7½ years after operation. There were 2 failures, one ended in nephrectomy, and the other, a case of giant hydronephrosis in a solitary kidney, was living 4 years later with a permanent nephrostomy. The result in each of the following 4 cases was fairly satisfactory.

CASE 26. Mt. Sinai Hospital No. 344,467. This 52 year old woman entered the hospital with high temperature due to a solitary infected hydronephrotic left kidney (Fig. 5). A right nephrectomy had been done for hydronephrosis in 1909. At operation (Dr. Edwin Beer) on October 22, 1932, the left ureter was found stenosed just below its junction with the pelvis. The pelvis was distended with frank pus.

¹ A secondary nephrectomy was recently done at another hospital.

² A plain film and excretory urograms made on December 2, 1940 revealed recurrent calculi with considerable hydronephrosis.

The stricture as resected and the cut end of the ureter was reimplanted into the pelvis over a splinting ureteral catheter. A portion of the redundant pelvis as then excised, the opening sutured, and a nephrostomy made.

The patient had a prolonged and stormy convalescence, marked by septic temperature, lith reported chills. Colon bacilli were recovered in the blood culture. The bacteremia was gradually overcome the patient making slow recovery and leaving the hospital 4 months after operation. She has lived fairly comfortably and has attended to her household duties for over 7 years, suffering occasionally from attacks of chills and fever. A retrograde pyelogram (Fig. 6) made in August, 1930, showed considerable dilation of the pelvis and ureter. She was still when last seen by Dr. W. Meschter early in 1940.

CASE 5. Beth Israel Hospital No. 69,995. This case was reported in some detail (1). At operation on January 8, 1935, the left renal pelvis as found to be very large and distended with straw-colored fluid. The entrance of the ureter into the pelvis was markedly constricted. The ureter was divided below the stricture, and reinserted into the most dependent portion of the pelvis as through a new opening. The ureter as sutured to the pelvis with five plain catgut sutures over a Garceau catheter which was brought out through the renal cortex and lumbar wound. The upper end of the ureter as split into flaps which were sutured to the inner surface of the pelvis. A nephrostomy as also made using a Frazier catheter.

The immediate postoperative result as good. Indigo carmine appeared from the left pelvis in 5 minutes in good concentration. Excretory and retrograde pyelograms showed, however, some tendency to narrowing at the ureteropelvic junction. The latest excretory urogram, made on March 2, 1936, showed mild degree of hydronephrosis. Lith clabbing of the calyces and diminished function. Early in 1940, the patient, refusing further ray study, stated that she as well.

CASE 7. Beth Israel Hospital No. 69,124. An 8 year old boy as admitted to the hospital. Lith pus and blood in the urine. Pyelography revealed right hydronephrosis with trapping at the ureteropelvic junction. At operation, on November 3, 1934, the pelvis as considerably dilated and there as marked stenosis of the upper catheters of the ureter. The stenosed area as resected. The transversely cut end of the ureter as reimplanted into the pelvis over a splinting No. 5 French ureteral catheter which was brought out through the lower pole next to nephrostomy catheter. The redundant pelvis as closed by placing sutures.

The immediate postoperative course was uneventful. However, when the splinting catheter as removed on the twentieth postoperative day the stoma did not function. A retrograde pyelogram, made through the nephrostomy revealed complete obstruction at the ureteropelvic junction. A cystoscope as then introduced into the pelvis through the nephrostomy stoma, but attempts to dilate the stoma from the pelvis downward were unsuccessful. 7 days later however, a catheter was easily passed from below up the right ureter into the pelvis. The stoma as then dilated on several occasions. Lith indwelling ureteral catheters. The wound healed promptly following removal of the nephrostomy tube on the thirty-sixth postoperative day. This boy has now been perfectly all for about 4 years after operation. The latest excretory urogram, made on March 14, 1940, showed good function and no progression of the hydronephrosis. The urine was clear.

CASE 8. Mt. Sinai Hospital No. 300,009. This case has recently been reported in detail (6). At operation on September 20, 1932, the left kidney and pelvis as found greatly dilated, and the upper half of the ureter as nearly

completely stenosed. The lower portion of the pelvis with the attached stenosed ureter as resected. The pelvis as closed with fine catgut and a No. 8 French soft catheter was inserted through the cortex into the pelvis and ureter as spinal. The ureter as reimplanted into the pelvis.

On the eighteenth postoperative day the tube as pulled upward out of the ureter into the pelvis. Indigo carmine, injected through the nephrostomy tube did not appear in the bladder. On the other hand, a catheter as easily passed from below through the anastomotic stoma into the pelvis. It as evident that the anastomosis as obstructed only to the downward passage of fluid. This as repeatedly confirmed by clamping the nephrostomy tube and injecting indigo carmine. Despite several trans-cystoscopic dilations, the efficient function of the stoma could not be established.

Three months after operation, a cystoscope as introduced through the nephrostomy stoma into the renal pelvis. A sickle-shaped fold of mucosa, noted just below the ureteropelvic junction, was thought to be the possible cause of the obstruction. This sickle-like fold as electro-coagulated, and a No. 5 French ureteral catheter as passed from below into the pelvis and out through the nephrostomy stoma. The nephrostomy tube was reinserted. Following several trans-cystoscopic dilations, the nephrostomy tube as again clamped off. The stoma as now functioning well. The nephrostomy tube as finally removed 5 months after operation, and the wound as dry within 24 hours.

This patient has been followed for 7 years. During this time, she re-entered the hospital on 6 occasions for cardiovascular disease and increasing hypertension. Lith 1937 splenic sympathectomy, crisis gangliotectomy, lumbar sympathectomy, and adrenal adrenalectomy are done on the right side. There as no lasting improvement. She as admitted to the Montefiore Hospital in 1939 for hypertension, and an excretory urogram showed good function of both kidneys. There are no renal symptoms.

Renal function after operation was fairly good in 4 of the 6 cases of section and reimplantation of the ureter. One of these (Case 26) a woman with an acutely infected solitary hydronephrotic kidney was living comfortably 7 1/2 years after operation. Another (Case 25) followed 4 years, shows some narrowing of the stoma with gradual decline in renal function. Although ultimately satisfactory, the 2 remaining cases developed complete obstruction to the downward flow of urine at the site of anastomosis immediately after removal of the splinting catheter. Pyeloscopy through the nephrostomy sinus in Case 28 revealed a valvular e-like mucosal fold, which was thought to be the cause of the obstruction. Following electro-coagulation of this fold and trans-cystoscopic dilatation from below the patency of the stoma was permanently re-established. The function of this kidney was still fairly good 7 years after operation.

In Case 27 the postoperative obstruction of the stoma was overcome by repeated trans-cystoscopic dilatation from below. Renal function was good 3 1/2 years later.

Unrelieved obstruction and infection were responsible for both failures. The first (Case 29

Fig. 5. Case 26. Excretory rogram before operation in solitary kidney.

Mt. Sinai Hospital No. 372,441) was solitary infected giant hydronephrosis due to stricture. The ureter was sectioned and reimplanted but the new stoma failed to function well. This patient was alive almost 4 years later with a permanent nephrostomy. The second unsuccessful case (Case 30. Mt. Sinai Hospital No. 45,327) a 1 year old boy left the hospital, presumably well, with a healed wound 22 days after operation. Two weeks later the kidney became quite tender and the temperature rose to 104 degrees. The lumbar wound opened spontaneously draining purulent urine. Nephrectomy was done.

The chief difficulty in the cases of section and reimplantation of the ureter was early postoperative obstruction at the site of anastomosis. This occurred in 4 of the 6 cases. Fortunately, however, the obstruction was successfully relieved in 2 cases, in one by electrocoagulation of mucosal

Fig. 6. Case 26. Retrograde pyeloureterogram made 7 1/2 years after section and reimplantation of ureter in solitary kidney.

valve followed by transcystoscopic dilatation, and in the other by dilatation alone. It seems apparent that an effort should be made at the time of operation to prevent the formation of a ureteral fold or cuff at the site of anastomosis. When possible the ureter should be split for distance of about 1 centimeter into 2 strips (Fig. 7). These are then fastened to the inner aspect of the pelvis by interrupted fine plain catgut sutures. Accurate apposition at suture line is obviously essential. More complicated techniques (11) have been suggested, but are rarely practical.

Fig 7 Diagram illustrating section and reimplantation of ureter and resection of pelvis

Lateral anastomosis In 2 cases, a side-to-side anastomosis was made between the upper ureter and the most dependent portion of the pelvis. When technically feasible, such a lateral anastomosis has the following advantages over section and reimplantation (13): (1) The vascular supply of the upper ureter is preserved by leaving the ureter attached to the pelvis, (2) there is less interference with peristalsis, (3) a side-to-side anastomotic stoma can be made much larger, thereby lessening the likelihood of early or late stricture.

CASE 31 Beth Israel Hospital No 75,048. This case has been previously reported in detail (13). At operation on June 20, 1935, the right kidney was greatly dilated. The ureter had a high anterolateral insertion with definite narrowing. A veil of fibrous adhesions extended over the ureteropelvic junction, causing an angulation at the point of insertion of the ureter. A side to side anastomosis was made, over a splinting No. 14 French rubber catheter. A nephrostomy was also done. The redundant pelvis was plicated, following scarification of its external wall. The postoperative course was uneventful, the nephrostomy

tube was removed on tenth postoperative day and splinting catheter on sixteenth postoperative day. Patient has been observed for 5 years with repeated excretory and retrograde pyelograms. Renal function is good, patient is well.

CASE 32 Beth Israel Hospital No 94,935 (12). This 31 year old man complained of dull pain in the right loin for 10 months and of severe pain in the left loin for 4 days. An excretory urogram revealed a large hydronephrosis on the left side and no visualization on the right (Fig 8). A retrograde pyelogram (Fig 9) revealed a huge functionless sac replacing the right kidney. At operation on August 2, 1937, a large left hydronephrosis was found. The ureter had a high lateral insertion, forming an obstructive angle. A side to side anastomosis was made over a splinting No. 8 French ureteral catheter, the catheter being brought out through the cortex. A nephrostomy and nephropexy were also done. The splinting catheter was removed on the twelfth postoperative day. On September 16, 1937, a right nephrectomy was performed. The left nephrostomy tube fell out on September 22, and the wound healed. The patient left the hospital on October 18, voiding well.

LINE OF STUDY

These patients with plastic operations on the ureters and ureter have established the following principles: (1) Free urinary drainage by means of a nephrostomy; (2) splinting of anastomosis parts by means of a catheter; (3) accurate approximation of sutured parts.

Free drainage is a prime requisite in the treatment of urinary infection from which most of these patients suffer. A nephrostomy should, therefore, be performed in all cases in which any extensive pelvic or ureteropelvic plastic procedure is done. The tube acts as a safety valve preventing undue internal tension on the suture lines. In addition, it may be used for the instillation of bactericidal solution.

Prolonged drainage is often desirable. The anastomosis is put to a practical functional test by clamping off the nephrostomy tube for several days before its final removal. Should the anastomosis fail to function satisfactorily the tube is again allowed to drain. This gives additional opportunity for edema and infection to subside and for trans cystoscopic dilatation of the stricture. In 2 cases (Cases 27 and 28), a cystoscope was introduced through the nephrostomy sinus for direct visualization of the pelvis and site of anastomosis. In one of these, endopelvic electrocoagulation of a valve-like mucosal fold was followed by the permanent re-establishment of patency of the stricture.

The authors believe that the nephrostomy tube should be left in place for at least 2 weeks and often for a much longer time. It should be removed only after the adequacy of the anastomotic opening has been proved and when the infection has been well controlled. The administration of drugs, such as sulfanilamide and sulfapyridine is frequently effective, especially after removal of the tube.

After operation made 36 years after attack of solitary kidney. Patient still alive and well 23 hours later. His severe pain in the back, fever and anuria. At cystoscopy the bladder was empty and an impassable obstruction was seen. The ureter 4 centimeters above its orifice was completely blocked. An immediate ureterotomy was performed and a catheter was inserted. The obstruction was probably due to a small, non-opaque calculus, but was not recovered. The ureteropelvic tube was then clamped off and the patient remained normal. A clamped-off nephrostomy tube was used as a safety valve for about a year. The tube was removed and the wound healed promptly. The patient afterwards had shown Bacillus coli, Bacillus pyocyaneus, and Bacillus lactic aerogenes. After use of sulfanilamide, urine became sterile. Blood non-protein nitrogen was 38 milligrams. An excretory urogram, June 1930 (Fig. 1) showed good function of left kidney. Patient still alive and working 3 years after operation.

The end result in the 2 cases of late ureteral obstruction was satisfactory. In Case 3 a pelvic plasty was also done. The function of the kidney operated on was good after the second case, the anastomosis of the solitary kidney. This patient is well with adequate renal function 3 years after operation.

may precipitate calculous formation when in contact with urine

SUMMARY

1 The results of 32 plastic operations on the renal pelvis and ureter have been reported and analyzed. In 5 cases, the ureter was reimplanted in the renal pelvis following accidental avulsion. The 27 remaining plastic operations were done for hydronephrosis due to obstruction at the ureteropelvic junction.

2 Relief of obstruction was the primary object of the surgical treatment of hydronephrosis. In some cases, the dilated pelvis was also resected or plicated.

3 The various types of plastic operations employed are discussed and evaluated, and illustrative cases are recorded in some detail.

4 Early postoperative obstruction at the site of anastomosis was encountered in 4 of 6 cases of section and reimplantation, and in 2 of 5 cases of reimplantation following accidental avulsion.

5 Transcystoscopic dilatation was effective in several cases in overcoming early postoperative obstruction.

6 Direct pyeloscopy through the nephrostomy sinus was done in 2 cases. In 1 instance, the

patency of the stoma was re-established, following electrocoagulation of a valve-like mucosal fold near the site of anastomosis.

7 Late stricture was observed in 1 case of section and reimplantation, 1 case of reimplantation following avulsion, and 1 case of Fenger pyeloplasty.

8 Side-to-side anastomosis of the ureter and pelvis, when feasible, appears preferable to section and reimplantation.

Fig. Excretory urogram made 36 years after side to-side anastomosis. Solitary kidney. Patient ell.

If readmitted 4 hours later with severe pain in the left loin, high fever and anuria. At cystoscopy the bladder as empty and an impassable obstruction as encountered in the left ureter 4 centimeters above its orifice. A nephrostomy as immediately performed and relieved the patient as painless old. This obstructive episode as probably due to small non opaque calculus, which, however as not recovered. The ureteropelvic stoma as dilated number of times from below. The nephrostomy tube as then clamped off and the patient voided normally. A clamped-off nephrostomy tube as left in situ as safety sh for about year. Thereafter as finally removed and the wound healed promptly. The urine cultures 1 shows times had shown *Bacillus coli*, *Bacillus pyocyaneus*, and *Bacillus lactis aerogenes*. After course of sulfanilamide urine became sterile. Blood non protein nitrogen as 35 milligrams. An excretory urogram, June, 1940 (Fig. 1) showed good function of left kidney. Patient ell and working 3 years after operation.

The end-result in the 2 cases of lateral anastomosis was satisfactory. In Case 31 in which a pelvic plication was also done the function of the kidney operated on was good after 5 years. In the second case, the anastomosis was made on a solitary kidney. This patient is well with adequate renal function 3 years after operation.

ANALYSIS OF STUDY

Increased experience with plastic operations on the renal pelvis and ureter has established the following principles: (1) Free urinary drainage by means of nephrostomy; (2) splinting of anastomosed parts by means of a catheter; (3) accurate apposition of sutured parts.

Nephrostomy. Free drainage is a prime requisite in the treatment of urinary infection from which most of these patients suffer. A nephrostomy should, therefore be performed in all cases in which any extensive pelvic or ureteropelvic plastic procedure is done. The tube acts as a safety valve preventing undue internal tension on the suture lines. In addition, it may be used for the instillation of bactericidal solution.

Prolonged drainage is often desirable. The anastomosis is put to a practical functional test by clamping off the nephrostomy tube for several days before its final removal. Should the anastomosis fail to function satisfactorily the tube is again allowed to drain. This gives additional opportunity for edema and infection to subside and for trans cystoscopic dilatation of the stoma. In 2 cases (Cases 27 and 28), cystoscope was introduced through the nephrostomy sinus for direct visualization of the pelvis and site of anastomosis. In one of these endopelvic electrocoagulation of a valve-like mucosal fold was followed by the permanent re-establishment of patency of the stoma.

The authors believe that the nephrostomy tube should be left in place for at least 2 weeks and often for a much longer time. It should be removed only after the adequacy of the anastomotic opening has been proved and when the infection has been well controlled. The administration of drugs, such as sulfanilamide and sulfa pyridine is frequently effective especially after removal of the tube.

The splinting catheter. A straight ureteral catheter is inserted into the ureter for a distance of about 10 centimeters below the site of anastomosis and brought out through the renal pelvis and cortex. It serves the double purpose of immobilizing the anastomosed parts and maintaining the new opening. The splinting catheter should be left in place for at least 7 days since its early removal may result in stricture or occlusion of the stoma.

Accurate apposition. Accurate suture of the mucosa and the muscularis in separate layers is recommended when possible by means of fine interrupted plain catgut sutures for the mucosa and fine interrupted chromic sutures for the outer layers. Non-absorbable suture materials are contra indicated since they act as foreign bodies and

may precipitate calculous formation when in contact with urine

USE OF THE IAG SCREW FOR INTERNAL FIXATION OF INTERTROCHANTERIC FRACTURES OF THE FEMUR

MELVIN A. CASBERG, M.D., St. Louis, Missouri

FROM the standpoint of medical literature one is impressed by the obscurity into which extracapsular fractures of the femur have fallen. Recent progress in the therapy of intracapsular fractures has so absorbed medical interests that there is a tendency to neglect an adjacent fracture of equal importance. Prior to Smith-Petersen's contribution to the therapy of fractures of the femoral neck, the capsule played an important rôle as a landmark of prognostic value. This factor was first emphasized by Sir Astley Cooper who distinguished between intracapsular and extracapsular fractures and defined the poor prognosis of the former and the much better prognosis of the latter. True as these facts are they have in many instances led to a certain therapeutic fallacy in the assumption that treatment of extracapsular fractures is relatively unimportant because union is inevitable. Though this assumed truism is correct in part it is better clarified by the additional statement that union is inevitable in those patients who survive sufficient period of time to permit such a process.

The study of mortality statistics in intertrochanteric fractures is rather disturbing and is prone to produce a somewhat pessimistic attitude. In the St. Louis City Hospital during 1937 the mortality rate for extracapsular fractures was

From the Department of Surgery, St. Louis City Hospital.

approximately 40 per cent while for intracapsular fractures it was 28 per cent (9). This difference is made possible by two definite factors: first, intertrochanteric fractures in general are associated with more shock and with greater trauma to the soft tissues as well as to the bone; second, the age of those suffering extracapsular fractures averages from 3 to 10 years above that of those with fractures of the femoral neck (11, 12). Intertrochanteric fractures usually show considerable trauma of the vastus lateralis, rectus femoris, and tensor fascia lata muscles with the extravasation of blood into the muscle bodies and even the presence of large intramuscular hematomas. This excessive tissue damage is the exception in fractures of the femoral neck where the trauma is localized fairly well within the joint capsule.

In recapitulation it might be stated briefly that to a certain extent the therapeutic problem presented by intracapsular fractures is that of union, whereas, in extracapsular fractures the problem of union is secondary to that of the maintenance of life.

In 1871 Hodgen described a swinging double inclined plane splint that is still employed by some surgeons in the therapy of extracapsular fractures. Though this method of treatment has produced excellent anatomical results in our hands, it requires the patient to remain in bed during the

FIG. 1. a, Roentgenograms taken on admission of W. W. (Case) male aged 5 years. Routine operation as performed. Complete reduction and fixation are shown in b and c. Patient as permitted to be up in wheel chair on twelfth day. Walked with the aid of crutches on the eighteenth day and bore weight with the aid of

crutches 5 weeks after operation. Eight weeks after operation the crutches were discarded and the patient walked using cane. d, taken 5 months after operation shows the amount of callus covering the tail of the screw. Patient followed for 5 months and has free motion of his fixed hip. (Operation August, 1930)

interim of immobilization, which averages about 10 weeks. This prolonged period of recumbency is a dangerous factor, especially in the aged. Various methods of fixation have been devised in order to permit the patient greater mobility. One of the better known is the well leg traction splint described by Roger Anderson. With this type of fixation the patient may be permitted a certain degree of mobilization almost immediately following reduction. Utilization of this principle in the St. Louis City Hospital (14) during the year 1938 to 1939 improved the mortality statistics slightly more than 10 per cent. Though there are certain disadvantages, the chief of which is the difficulty in rehabilitation due to pain in the joints, well-leg traction affords good fixation for a large percentage of intertrochanteric and subtrochanteric fractures.

Key, in an effort to reduce the high mortality rate in trochanteric fractures of the femur, resorted to internal fixation of these by the insertion of the Smith-Petersen nail. This method did not prove entirely satisfactory, for Key states, "In the beginning we had hoped for a method which would fix these trochanteric fractures to the same degree and afford the same freedom from casts and splints and permit the patient to be gotten out of bed soon after the operation, as is the case in fractures through the neck of the femur which have been nailed. However, it seems evident that this is not possible, because of the tendency to comminution and of the rather wide variation in the type of fracture encountered."

Fig 2 Photograph (Case 1) taken 3 weeks after operation to demonstrate free motion of the hip

THE LAG SCREW

It is not the purpose of this paper to discuss the advantages or disadvantages of the flanged nail, pin, or screws in the fixation of femoral neck fractures, for, in the hands of their individual masters each has proved successful. It is the purpose of this paper, however, to discuss the Leydig and Brookes (10) modification of the Henderson lag screw as a method of fixation of certain selected intertrochanteric fractures. This lag screw cannot be used indiscriminately on all extracapsular fractures and the cases must be selected carefully from the standpoint of the type of fracture. Subtrochanteric and markedly comminuted intertrochanteric fractures do not lend themselves to this type of fixation, for it is essential to have a

Fig 3 a, Roentgenogram taken on admission of M. S. (Case 2), female, aged 69 years. b and c were taken immediately after operation. The patient was up in a wheel chair on the fourth day, and was walking with the aid of crutches just 2 weeks after operation. Weight bearing was commenced 5 weeks after operation and the crutches were discarded 5 weeks later, though at times one crutch was used when the patient had to walk more than usual. Motion at the hip was free and painless. Five months after operation the patient was using a cane but was able to get about quite well. (Operation February, 1940)

Fig. 4. a, Roentgenogram taken on admission of W. W. (Case 3), male, aged 73 years. Operation as performed in the routine manner and postreduction plates, b and c, show position of the lag screw. (Operation February 1940)

portion of the greater trochanter attached to the distal fragment as a point of purchase for the flange of the screw.

The advantages of this lag screw in fixation are chiefly those of early mobilization of the patient. This factor entails not only the reduction of the mortality rate and a great decrease in the period of hospitalization, but also added comfort and an improvement in the morale of the patient who is not lumbered with casts or traction apparatus of any sort.

Fig. 5. Case 3. Patient up in bed chair on fourth day showing type of dressing; the ACE bandage has been removed.

The instrument of fixation is made up of a unit of three separate parts: the lag screw, which is inserted well into the femoral head; a rectangular flange, which grasps the lateral surface of the greater trochanter and femoral shaft; and a nut, which when applied to the tail of the screw over the flange impacts and immobilizes the fractured fragments. The shaft of the screw measuring 4 inches in length terminates in a head made up of a wide wood-screw twist of six turns which penetrates and grasps the trabecular bone of the femoral head. The threaded tail of this instrument contains a slot which is adapted to receive the brace during its insertion and also to lock the flange to prevent its rotation after insertion. The rectangular flange, measuring five-eighths of an inch wide by two and a quarter inches long, is sufficiently large to afford a distribution of the lines of force over a wide surface of bone along the lateral portion of the greater trochanter and femoral shaft. In addition to this armamentarium a drill is needed to penetrate the cortex of the bone prior to insertion of the screw and a wrench for the turning of the nut.

THE TECHNIQUE OF OPERATION

One hundred milligrams of novocain is injected to produce spinal anesthesia, and an arthrotomy is performed after the method described by Cubbins and his co-workers. The skin incision extends from a point approximately 1 inch inferior to the anterior iliac spine, distally in vertical plane about 8 inches, and then curves laterally a distance of some 5 inches. A cleavage plane is then sought lying between the tensor fascia lata on the lateral side and the sartorius on the medial side. The insertion of the former muscle into the fibiofemoral tract of the fascia lata is then divided at

Fig 6 Case 3 Crutches used 2 weeks after operation, without weight bearing Three weeks after operation there is complete and painless motion of the involved hip, a, b, c

Crutches were discarded 8 weeks after operation and cane was used for 2 weeks When last seen the patient was walking well and without a limp

right angles so that the skin and the underlying muscle can be turned laterally as a flap By the retraction of the rectus femoris and sartorius muscles medially the joint capsule is readily identified and a cruciate incision is made to expose the femoral neck and head Very little bleeding is encountered if the branches of the lateral femoral circumflex vessels are identified and ligated as they pass through the operative field The vastus lateralis muscle originating from the lateral surface and base of the greater trochanter is then split in a vertical plane, and a mastoid retractor is placed so as to expose the shaft of the femur in this region

When the fracture site has been exposed and reduced by the Leadbetter maneuver, a drill hole is made from the lateral surface of the femoral shaft about 1 inch distal to the base of the greater trochanter, extending through the cortex and partially into the head of the femur After the desired length is determined by direct measurement, the lag screw is inserted under visual surveillance, the exposed femoral head and neck being used as landmarks The flange is then applied and the

nut is tightened so as to reduce and hold the intertrochanteric fracture firmly It is important that the flange be bent to fit the lateral contour of the bone without the interposition of soft tissues, for, should this be neglected, necrosis of the crushed soft tissues will result in the loosening of the screw

The only deep structures which require suturing are the joint capsule and the insertion of the tensor fascia lata muscle The remaining split muscle planes approximate themselves quite readily without fixation Black silk is used throughout as a suture material Before the closing of the wound, about 10 grams of sulfanilamide powder are sprinkled into the joint cavity and depths of the wound An ACE bandage is applied over the sterile dressing as a hip spica in an effort to eliminate any possible dead space The operative procedure consumes from 30 minutes to 1 hour depending upon the type of fracture, the ease of reduction, and the rapidity of fixation Spinal anesthesia affords very good relaxation which is an important factor in approximation of the fragments In our experience the operation has not seemed to cause shock and the patients in retro-

Fig. 4. a, Roentgenogram taken on admission of W. W. (Case 3), male, aged 73 years. Operation was performed in the routine manner and postreduction plate, b and c, show position of the lag screw. (Operation February, 1940)

portion of the greater trochanter attached to the distal fragment as a point of purchase for the flange of the screw.

The advantages of this lag screw in fixation are chiefly those of early mobilization of the patient. This factor entails not only the reduction of the mortality rate and a great decrease in the period of hospitalization, but also added comfort and an improvement in the morale of the patient who is not encumbered with casts or traction apparatus of any sort.

Fig. 5. Case 3. Patient up in bed chair on fourth day showing type of dressing; the ACE bandage has lag been removed.

The instrument of fixation is made up of a unit of three separate parts: the lag screw which is inserted well into the femoral head, rectangular flange which grasps the lateral surface of the greater trochanter and femoral shaft and a nut, which when applied to the tail of the screw over the flange impacts and immobilizes the fractured fragments. The shaft of the screw measuring 4 inches in length terminates in a head made up of a wide wood-screw twist of steel turns which penetrates and grasps the trabecular bone of the femoral head. The threaded tail of this instrument contains a slot which is adapted to receive the brace during its insertion and also to lock the flange to prevent its rotation after insertion. The rectangular flange measuring five-eighths of an inch wide by two and a quarter inches long, is sufficiently large to afford a distribution of the lines of force over a wide surface of bone along the lateral portion of the greater trochanter and femoral shaft. In addition to this armamentarium drill is needed to penetrate the cortex of the bone prior to insertion of the screw and a wrench for the turning of the nut.

THE TECHNIQUE OF OPERATION

One hundred milligrams of novocain is injected to produce spinal anesthesia, and an arthrotomy is performed after the method described by Cubbins and his co-workers. The skin incision extends from point approximately 1 inch inferior to the anterior iliac spine distally in a vertical plane about 8 inches, and then curves laterally distance of some 5 inches. A cleavage plane is then sought lying between the tensor fascia lata on the lateral side and the sartorius on the medial side. The insertion of the former muscle into the iliotibial tract of the fascia lata is then divided.

Fig 6 Case 3 Crutches used 2 weeks after operation, without weight bearing Three weeks after operation there is complete and painless motion of the involved hip, a, b, c

Crutches were discarded 8 weeks after operation and cane was used for 2 weeks When last seen the patient was walking well and without a limp

right angles so that the skin and the underlying muscle can be turned laterally as a flap By the retraction of the rectus femoris and sartorius muscles medially the joint capsule is readily identified and a cruciate incision is made to expose the femoral neck and head Very little bleeding is encountered if the branches of the lateral femoral circumflex vessels are identified and ligated as they pass through the operative field The vastus lateralis muscle originating from the lateral surface and base of the greater trochanter is then split in a vertical plane, and a mastoid retractor is placed so as to expose the shaft of the femur in this region

When the fracture site has been exposed and reduced by the Leadbetter maneuver, a drill hole is made from the lateral surface of the femoral shaft about 1 inch distal to the base of the greater trochanter, extending through the cortex and partially into the head of the femur After the desired length is determined by direct measurement, the lag screw is inserted under visual surveillance, the exposed femoral head and neck being used as landmarks The flange is then applied and the

nut is tightened so as to reduce and hold the intertrochanteric fracture firmly It is important that the flange be bent to fit the lateral contour of the bone without the interposition of soft tissues, for, should this be neglected, necrosis of the crushed soft tissues will result in the loosening of the screw

The only deep structures which require suturing are the joint capsule and the insertion of the tensor fascia lata muscle The remaining split muscle planes approximate themselves quite readily without fixation Black silk is used throughout as a suture material Before the closing of the wound, about 10 grams of sulfanilamide powder are sprinkled into the joint cavity and depths of the wound An ACE bandage is applied over the sterile dressing as a hip spica in an effort to eliminate any possible dead space The operative procedure consumes from 30 minutes to 1 hour depending upon the type of fracture, the ease of reduction, and the rapidity of fixation Spinal anesthesia affords very good relaxation which is an important factor in approximation of the fragments In our experience the operation has not seemed to cause shock and the patients in retro-

Fig. 7. a, Roentgenogram taken on admission of E. C. (Case 4) male aged 53 years, showing considerable comminution of intertrochanteric region. Routine operation with insertion of lag screw as performed under direct vision. Results are shown in b and c. The patient was up in wheel chair on the tenth day and was walking with the aid of crutches 3 weeks after operation. Three weeks later weight bearing was permitted and 6 weeks after operation he was walking without support. Motion was free except for abduction which was somewhat limited.

spect do not complain of discomfort resultant from this procedure.

The postoperative program followed is to have the patient propped up in bed 12 hours after the operation. The lower extremities are not encumbered by any traction apparatus and are left to roll freely about in bed. By the end of the second week, and in most cases within the first week, the patient is up in a wheel chair for short periods daily. Approximately 2 to 3 weeks after operation the patient is walking with the aid of crutches without weight bearing and after a period of 5 to 6 weeks weight bearing is permitted. The crutches are discarded in about 8 to 9 weeks and a cane is used if the patient so desires. Thus the patient with an intertrochanteric fracture is rehabilitated within a period of about 2 months.

EVALUATION

As in the case of the Smith-Petersen nail insertion of the lag screw may be accomplished in one of two ways either through a small lateral incision over the base of the greater trochanter in which case the progress of the screw is determined by repeated roentgenograms, or by direct vision through exposure of the fracture site and the femoral neck and head. The lag screw was primarily devised for insertion by the former method, but for reasons to be discussed, these cases herein presented were reduced and immobilized by the latter technique.

Brittain in discussing the disadvantages of the open operation and insertion of the Smith-Petersen nail under direct vision raised the following objections: (1) Complete reduction by means of open operation is by no means certain. (2) The operation is a difficult one and undoubtedly carries a certain mortality. (3) Radiology on the oper-

ating table when there is a large incision, undoubtedly exposes the patient more to risks of infection than when the incision is confined to one-half inch. (4) There is frequently a certain amount of fibrosis associated with the opening of the capsule of the hip joint with resultant limitation of motion.

In the St. Louis City Hospital prior to August, 1939, the vast majority of the fractures of the femoral neck had been nailed by the closed method, but since that time most of the fixations have been accomplished by the open operation. This latter exposure afforded such an excellent view of the fracture site that it was adopted for the introduction of the lag screw as well. Though the points raised by Brittain refer specifically to fixation of fractures of the femoral neck by the Smith-Petersen nail, the same objections might well be raised to the open fixation of intertrochanteric fractures with the lag screw. Granted that the technique of open operation is somewhat more difficult, this factor should not be used as an excuse for its rejection because actual visualization of the fracture site affords not only a better opportunity for exact reduction and fixation but also permits testing of the solidarity of the immobilized fragments. This last is accomplished by motion of the thigh while observing the point of fracture. There is no need for radiological apparatus in the operating room for the course of the screw can be determined by direct measurement of the exposed femoral head and neck. Thus there is need for only two sets of roentgenograms, one before operation to diagnose the type of fracture and one after the operation to verify the success of fixation.

One of the hazards of orthopedic surgery has been infection and there are few fields of surgery

in which this complication can cause greater havoc. Jensen and his co-workers have presented a series of compound fractures in which the local implantation of sulfanilamide greatly reduced the percentage of wound infections. Stimulated by this report a policy was adopted of implanting about 10 grams of sulfanilamide powder in the operative wound, and this simple but effective measure has proved to be of definite value in the prevention of infection.

It may appear to some that arthrotomy is an unnecessary procedure because intertrochanteric fractures are extracapsular in position, yet, in order to direct the screw accurately and determine the depth of insertion, the femoral neck and head must be exposed. Experience both with the lag screw and Smith-Petersen nail has given no reasons to indicate that arthrotomy has resulted in a lack of free motion which might be ascribed to fibrosis of the joint capsule.

The limitations of this method of fixation are well recognized, for not every type of trochanteric fracture can be immobilized by the lag screw. In order to compete with extracapsular fractures the surgeon must be familiar with a varied armamentarium which should also include such factors as the Hodgen splint, varieties of the Whitman cast, and well leg traction. Each case may then be investigated from the standpoint of the type of fracture, age, economics, etc., and the final verdict thus determined. Since union of intertrochanteric fractures is the rule it is possible to determine the end-results at a much earlier date than is the case in femoral neck fractures, in which bone absorption and nonunion are encountered as complications. It is not necessary to remove the lag screw after union has occurred, though this is readily accomplished through a small incision over the tail of the screw. In certain cases the projecting tail of the screw is covered with a bone callus which tends to eliminate this as a possible source of irritation.

CONCLUSIONS

1 The mortality rate in intertrochanteric fractures of the femur is greater than that in fractures of the femoral neck.

2 Recent medical literature stresses the therapy of intracapsular fractures to the relative neglect of trochanteric fractures.

3 Four cases of intertrochanteric fractures of the femur are presented in which the lag screw was used as a method of internal fixation.

4 It is believed that in selected cases this procedure will result not only in a reduction of the mortality rate but also in a much shorter period of hospitalization.

5 It would appear that best fixation is obtained by open reduction and insertion of the lag screw under direct vision.

COMBINED TRACTION COMPRESSION METHOD FOR THE TREATMENT OF BICONDYLAR FRACTURES OF THE TIBIA

ROBERT A. WISE, M.D. F.A.C.S. New York, New York

COMBINED traction and compression are required for the satisfactory reduction of bicondylar fractures of the tibia. These injuries are produced by a force which drives the hard cortical shaft of the tibia into the soft expanded cancellous portion of the tibial plateau, resulting in a splitting, separation and depression of the condyles. It is clear that any satisfactory method of treatment must correct the upward thrust of the tibial shaft as well as reduce the lateral displacement and depression of the tibial condyles. Traction alone without compression of the condyles is insufficient, compression without traction will result in unsatisfactory alignment of the fragments. A combination of both traction and compression is necessary. Moreover these forces must be applied in such a manner that they can be maintained until the fracture is firmly united. To apply compression by means of a carpenter's clamp and then, of necessity to release it will frequently result in a recurrence of the deformity. To maintain traction by means of a casting is impossible.

It is the purpose of this paper to present a simple method of applying continuous traction and compression for the reduction and fixation of displaced bicondylar fractures of the tibia. The traction is obtained by means of a Kirschner wire which is inserted through the calcaneus; the compression, by sleeved wire (x) inserted through the tibial condyles.

The following case report demonstrates the application of this method.

CASE REPORT

J. J. male, aged 27 years, as admitted to Knickerbocker Hospital on June 4, 1939. He stated that while riding bicycle the front wheel suddenly caught in its frame and he was thrown forward striking his right leg against the curb.

Examination revealed swollen, tender, discolored right knee. There was evident swelling of the tibial plateau and the lateral condyle and head of the fibula were abnormally prominent. There was moderate valgus deformity and slight external rotation of the leg. The knee joint was unstable with wide range of anteroposterior and lateral mobility.

Roentgenogram (Fig. 1) showed comminuted bicondylar fracture of the tibia with marked outward displacement of the lateral and depression of the medial condyle.

From the Fracture Service of Knickerbocker Hospital.
Read before the Surgical Section of the New York Academy of Medicine, October 4, 1940.

Russell traction was applied to the right leg for 6 days. This resulted in improvement in the alignment of the fragments but with no change in the outward displacement of the lateral condyle or the depression of the medial condyle. It was evident that compression of the condyles, as well as traction in the long axis of the leg, was necessary.

Combined continuous compression and traction as applied on June 3, 7 days following the injury. The compression sleeve used consists of three parts: (1) Kirschner wire of medium diameter to which is added fixed metal head and washer; (2) metal sleeve which slips over the leg; and (3) threaded collar with set screw and nut.

Technique. Under nitrous-oxide-oxygen anesthesia, Kirschner wire was inserted through the calcaneus and traction as applied to the leg. An incision one centimeter in length was made over the lateral tibial condyle midway between its anteroposterior diameter and 5 centimeters below its articular surface. The sleeved wire with the fixed head and washer as then inserted through the upper end of the tibia, emerging on the inner side of the knee through the medial condyle, the washer placed against the periphery of the lateral condyle. A centimeter incision was made at the point of exit and the metal sleeve slipped over the wire and brought into contact with the medial condyle. The threaded collar was then placed on the wire and fixed by means of its set screw. The nut was turned, and as it approached the medial condyle compression was exerted through the sleeve, forcing the condyles together.

Roentgenogram (Fig. 2) showed marked improvement in the position of the fragments. The leg was placed on a Boehler frame with pounds of traction applied through the calcaneus and the compression maintained by means of the sleeve (Fig. 3).

After-care. Raising and massage of the quadriceps exercises were begun early. The compression force was unchanged but the traction was reduced to 5 pounds after 5 weeks. Seven weeks after reduction, under local anesthesia, the compression wire was removed from the upper end of the tibia and the Kirschner wire was withdrawn from the calcaneus. A plaster casting was applied from the toes to the mid thigh, with the knee in 5 degrees of flexion. The patient was allowed up on crutches and discharged 4 days later. The casting was bivalved 9 weeks after reduction and removed daily for massage and active knee motion. The incisions at the upper end of the tibia had healed per primam. Three months after reduction, a walking caliper brace was applied. Unsupported weight bearing was allowed 6 months after the injury. Examination of the patient in May 1940, 10 months after reduction, revealed stable, painless knee with complete extension and 35 degrees of flexion (Figs. 4 and 5). There was no anteroposterior motion of the knee joint and only slight lateral mobility. Roentgenogram (Fig. 6) showed firm healing of the fracture.

The method described makes possible the continuous action of the two forces required. Continuous compression could be obtained by bolt but

the sleeved-wire has the advantage of simplicity of insertion and removal with minimal trauma to the cancellous bone

The points chosen for the insertion and exit of the compression wire will vary with different displacements and should be determined after careful study of the roentgenograms. In some cases the wire will be introduced 1 centimeter below the articular surface, in others a position several centimeters lower will effect the best compression. As the normal landmarks about the knee are often obliterated by soft part swelling, it is advisable to place a marker across the upper end of the tibia in what is considered the desired position and to take

an anteroposterior roentgenogram. The correct position in the longitudinal plane for the insertion of the wire can be easily determined from the position of the marker. In the vertical plane, the wire should be introduced into the center of the tibia, a point easily selected by means of palpation.

Arthrotomy is indicated in many badly displaced bicondylar fractures because of severe injury to the semilunar cartilages and lateral ligaments. Because the methods for reduction and fixation of the bony fragments at open operation have not always been successful, it is suggested that if arthrotomy is performed, the displaced

condyles may be reduced and fixed by the combined traction-compression method where is here described.

SUMMARY

1. A method combining continuous traction and compression is reported.

2. The value of the combined traction-compression principle in the reduction and fixation of

a bicondylar fracture of the tibia is demonstrated.

3. Traction is obtained through a Kirschner wire in the calcaneus.

4. Compression is applied by means of a compression sleeve which is inserted through the condyles.

RELATION OF PYELONEPHRITIS TO TOXEMIAS OF PREGNANCY

GLORGE C PRATHER, M D, F A C S, and WESTON SEWALL, M D,
Boston, Massachusetts

DURING recent years Peters (8-11) has been foremost in presenting data which might suggest pyelonephritis as a possible cause of toxemia of pregnancy, the general term describing certain complications which occur during gestation, whose symptoms at times include headache, visual disturbances, irritability, nausea, vomiting, epigastric pain, rapid gain of weight, and, perhaps, convulsions. Frequent clinical findings are edema, hypertension, and albuminuria. It is evident that many of the signs and symptoms of toxemia are also common in various types of renal disease. So many theories of the cause of toxemia have been advocated that it is evident that no one yet knows the answer to this problem.

General agreement has existed during the past few years that vascular change (4) is the basic pathological conception. Pathological changes in toxemia, as in essential hypertension, are found more commonly in the kidneys than in other organs of the body (3). While the changes accompanying these troubles in the kidney are somewhat variable in both their extent and their variety, Fahr, Bell, Baird and Dunn have reported thickening of the capillary walls of the glomeruli due particularly to thickening of the basement membrane in the capillary tufts. The increase in bulk produced by the thickened connective tissue membrane contributed to the obstructive effect in the capillary.

Although it is not certain what initiates this clinical or pathological condition in pregnant women without previous vasculorenal disease, the symptoms which the toxemias and certain renal diseases possess in common have led to a broader conception of the problem. The more comprehensive point of view can be visualized if one compares the classification of toxemias today with that of 20 years ago (14). At that time nephritic toxemia, pre-eclamptic toxemia, and eclampsia formed the only subdivisions of this subject. Contrast today's proposed classification (Table I) recently offered by Kellogg and Reid,

From the urological and obstetrical departments of the Boston Lying-in Hospital.

Read June 6, 1930 before the American Association of Genito-Urinary Surgeons.

which is cognizant of the fact that renal conditions existing during pregnancy may simulate pre-eclampsia and eclampsia.

Pyelonephritis as the initial lesion of a trend resulting in progressive deterioration of the kidney has been emphasized by Weiss and Parker, by Longcope, and by others interested in the relation of chronic pyelonephritis to hypertension. Since the albuminuria and hypertension of toxemia of pregnancy may be associated with renal disease, it seems reasonable to investigate the incidence of toxemia following pyelonephritis in pregnancy. Mussey and Lovelady recently stated that pyelitis of pregnancy is not prone to cause pre-eclamptic toxemia or eclampsia. Although we may not agree with all of the conceptions and

TABLE I—CLASSIFICATION OF TOXEMIAS OF PREGNANCY—KELLOGG AND REID—1930

Group 1	
I	Hypertensive or arterial vascular disease
a	Benign
	Mild
	Severe—cardiorenal
b	Malignant
II	Renal disease
a	Glomerulonephritis
	Acute
	Chronic
	Mild
	Severe
b	Pyelonephritis
	Acute
	Chronic
c	Other forms of severe renal disease. Nephrosis, polycystic kidneys, and other congenital anomalies of the kidneys
Group 2	
I	Mild pre-eclampsia
II	Severe pre-eclampsia (Preconvulsive)
III	Eclampsia
Group 3	
I	Unclassified (unknowns)
a	Those patients in whom a definite diagnosis can not be made to allow them to fall into Group A or B (i.e., glomerulonephritis suspected)
b	Many will fall into the above known groups post partum but insufficient data before or in the early months of pregnancy make it imperative to exclude them from statistical data except if autopsy findings ultimately allow them to be put in either Group A or B

Fig. 1. a, Primipara with left pyelonephritis in 01. b, Same patient in early pregnancy in 030. The urine

b

showed no infection. c, Same patient immediately post partum in 030. Late pregnancy changes not yet resolved.

conclusions presented by Peters, we acknowledge the importance of his success in focusing attention to the possible association of pyelonephritis to the toxemias of pregnancy. Of 320 cases with a diagnosis of toxemia studied by Peters, 41 or 13 per cent, had had pyelitis or pyelonephritis. The opinion was verified by autopsy in 11 of the 41 cases. Of 25 toxemia patients who came to autopsy during a 14 year period, Peters reported that in 11 or 44 per cent, pyelonephritis was found. However, closer scrutiny of the autopsies

data which were presented would lead us to believe that only 4 of the 25 cases, approximately 16 per cent, showed chronic pyelonephritic changes.

The important data supplied by Peters have been rather startling because of the relatively high incidence of pyelonephritis which he found in toxemia. We therefore recently decided to review a series of patients at the Boston Lying-In Hospital who we feel had pyelonephritis associated with at least one pregnancy and who

Fig. 2. a, left. Patient with pyelonephritis in sixth month of pregnancy. Moderate pregnancy changes in right ureter and kidney. b, Same patient one year later during another pregnancy. Urine is uninfected. There is less anatomical change than during the previous pregnancy.

Fig 3 a, A quadrupara with pyelonephritis on the right side in 1930 during the eighth month of a pregnancy b, The same patient with pre-eclampsia during a preg-

nancy in 1933 c, The same patient postpartum There is evidence that a good anatomical recovery was made from the changes of pregnancy

returned during a later year in a pregnant state Such a review may give data as to how frequently toxemia follows the pyelonephritis associated with pregnancy

The data for this paper are based on the observations and records of 72 patients with pyelonephritis and pregnancy during the years 1930 to 1939 Only patients who had one or more pregnancies subsequent to the pregnancy with pyelonephritis were used Of the 72 patients, 42, or 58.3 per cent, were primipara, 30, or 41.7 per cent, were multipara Seventy had pyelonephritis dur-

ing pregnancy, 2 had acute pyelonephritis immediately postpartum while in hospital Forty-three, or approximately 60 per cent, were in a febrile phase while in hospital, leaving 29, or 40 per cent, in an afebrile, subacute stage at the time of observation

Further incidental clinical data of the patients forming our group indicated that pyelonephritis affected the right kidney in 48.5 per cent of the cases, the left kidney in 19.7 per cent of the cases, and in 31.8 per cent the inflammatory process was bilateral

Fig 4 a, Tripart with bilateral pyelonephritis in 1930 b, Same patient with toxic separation of placenta during a

later pregnancy c, Same patient at a later period non-pregnant

Fig. 5 a, Tripura, in 935, fifth pyelonephritis in the sixth month of pregnancy. The bony pelvis is abnormal. b Same patient in 936, during her fifth pregnancy. Although there is bilateral hydronephrosis and hydroureter

the urine remained sterile. c, Same patient postpartum after her fifth pregnancy. It is evident that there has been good anatomical recovery of the kidneys and the ureters.

The records of these patients suggested a past history of pyelonephritis in 16.6 per cent, half of whom had had the disease with a previous pregnancy, the remaining half having had pyelonephritis before the onset of any pregnancy.

Our diagnoses were made by cystoscopic studies in 34 patients, clinical and laboratory findings in 38. Laboratory data revealed a bacillary type of urinary infection in 91.5 per cent, gram positive cocci in 5.1 per cent, bacilli and cocci in 3.6 per cent.

Renal function tests were not done as routine during the hospital admission for pyelonephritis, so that we do not have sufficient data from urea clearance studies and concentration tests to draw any conclusions. The nonprotein nitrogen in 40 cases was reported as 21 to 33 milligrams per 100 cubic centimeters of blood, and the blood ureic acid in 38 cases was recorded as 2.3 to 4.1 milligrams per 100 cubic centimeters of blood. Although we realize that blood chemistry does not detect slight diminution of renal function, it is evident that renal decompensation did not exist.

X-ray data were obtained in 55 patients—26 having had intravenous pyelography, the remaining 29 retrograde study. The dilatation of the ureters and pelvis (Fig. 1) and the ureteral kinks were not extraordinary to anyone familiar with urological changes during pregnancy. The renal and ureteral dilatation in the subsequent pregnancy (Fig. 2) never exceeded that found with the first pyelonephritis, irrespective of whether the subsequent pregnancy was normal or compli-

cated by recurrent pyelonephritis or toxemia. In general, patients with toxemia appear to have less ureteral and pelvic distortion (Figs. 3 and 4) by intravenous pyelography than the normals. Extreme degrees of distortion and dilatation were observed frequently in patients with normal urine sediments and without clinical signs (Fig. 5) of pyelonephritis. The anatomical recovery following the physiological dilatation of pregnancy is impressive but is subject to continued distortion if abnormalities were present before pregnancy or if inflammatory changes in the pelvis or ureter go on to fibrosis.

Our primary interest in this study was not the findings in pyelonephritis, but rather how many later pregnancies were normal and how many were complicated by toxemia.

Of the 72 patients with pyelonephritis 47 or 65.28 per cent, had normal pregnancies at a later date. As a matter of fact, 5 of the 47 had further multiple normal pregnancies—a total of 67 normal pregnancies in 47 patients. The time interval between the pyelonephritis during pregnancy and the normal pregnancy varied between 2 and 9 years, an average interval of 3.62 years. Frequent blood pressure recordings were normal during the subsequent pregnancies in all 47 patients. Blood pressures during the normal later pregnancies were about the same as during pyelonephritic pregnancies in 34 patients. In 13 the readings averaged lower during normal pregnancy. Six of 47 patients had the slightest trace of albumin in a voided specimen just prior to term.

One normal pregnancy following a pyelonephritic pregnancy does not guarantee freedom from complications during a still later pregnancy. This fact is illustrated in 6 patients who developed pyelonephritis after having a normal intervening pregnancy, and 1 patient who developed toxemia of pregnancy after a normal intervening pregnancy.

Interest, of course, will be centered on those who had pyelonephritis during one or more pregnancies, and who in a later pregnancy developed toxemia. In our series of 72 patients who had pyelonephritis associated with pregnancy, and who later returned to hospital in a pregnant state, 9, or 12.5 per cent, developed toxemia. The hospital diagnosis as to the type of toxemia was pre-eclampsia in 8, eclampsia in 1, (toxic separation of the placenta with albuminuria in 1). The time interval between pyelonephritis in pregnancy and the toxemic pregnancy ranged between 1 and 9 years. The average interval was 3.45 years, essentially the same interval as mentioned above in discussion of the group who had subsequent normal pregnancies following pyelonephritis. Apparently the time interval is not important. Our data as to whether the urinary infection had cleared during the interval are incomplete. We are certain that of the 9 who developed toxemia, 2 patients had urines free of infection during the interval between pregnancies and 2 were known to remain infected. At the time of the pyelonephritis 4 were primiparas, 5 were multiparas. At the time of toxemia 3 were secundipara, 1 was a tripara, 1 was a quadripara, 3 were quintipara, and 1 was a decipara. The toxemia occurred in the first pregnancy following pyelonephritis of pregnancy in 7 of the 9. In 2 there was an intervening pregnancy with no indication of toxemia.

Renal function tests during the pregnancy with toxemia were not done as routine except for the nonprotein nitrogen, which was normal as one might expect. Table II shows the blood pressure readings in 9 patients with pyelonephritis who later developed toxemia. The toxemia was sufficiently severe in 5 of the 9 patients to warrant interruption of the pregnancy.

Because of the current interest in the relation between blood pressure and pyelonephritis, we present a meager amount of data which may be of interest. Of the 72 patients in our series there were 8, or 11.1 per cent, who during the pregnancy with pyelonephritis had, on one or more occasions, a blood pressure recorded of 140/90 or over. Four were in the ninth month of pregnancy, 2 were in the seventh month, 2 were in the sixth

TABLE II — BLOOD PRESSURE AND ALBUMIN

Case Number	Pyelonephritis			Toxemia		
	Year	Blood Pressure	Albumin	Year	Blood Pressure	Albumin
2	1935	118/74		1939	134/78	SPT ST
27	1937	110/86		1939	132/94	SPT
30	1936	150/110	1 ST	1939	150/84	LT
42	1930	108/80		1933	144/110	
47	1930	94/58		1931	170/114	LT
49	1930	108/80		1933	146/98	1 ST
64	1930	140/		1931	80/68	T
65	1930	10 /62		1933	(Hemorrhage) 105/65	SPT
71	1930	114/60		1939	170/100	

month. Three of the 8 had a past history of renal disease. The 8 patients just mentioned had 10 pregnancies following the one in which pyelonephritis and hypertension were observed. The time interval was 1 to 6 years, an average of 3.2 years. In the 10 pregnancies which followed, recurrent pyelonephritis developed in 5, but blood pressures remained below 130/85 at all examinations. Three normal pregnancies followed with all blood pressure readings 128/80 or below. Two developed toxemia with hypertension. In a follow-up of the 8 patients mentioned after an average interval of 3.7 years from the time of pyelonephritis with hypertension, all had blood pressure readings below 135/84. Only 1 patient had the slightest possible trace of albumin. Thus, in a small group of 8 patients with pyelonephritis and hypertension, toxemia developed at a later pregnancy in 25 per cent, which is double the incidence following pyelonephritis in general during pregnancy. However, our limited data fail to suggest any permanent elevation of blood pressure following pyelonephritis during a 3 year follow-up period.

On the basis of maternity hospital admissions, pyelonephritis has an incidence of 1 to 2 per cent (12). By the same standards, toxemia of pregnancy has an incidence of about 10 per cent (15). We have found that toxemia of pregnancy follows pyelonephritis associated with pregnancy in 12.5 per cent.

Not feeling competent to make accurate deductions from these simple figures we called upon Mr. Philip Rulon, who teaches statistics at Harvard University, for advice. His informal opinion was as follows:

A. The incidence of pyelonephritis in pregnancy is 1 to 2 per cent.

B The incidence of toxemia in pregnancy is 10 per cent.

The incidence of toxemia of pregnancy following pyelonephritis associated with previous pregnancy is 12.5 per cent.

Pyelonephritis is not a cause of toxemia of pregnancy.

The data for the proper deductions as to possible cause and effect should be tabulated in the manner here used, namely, to see how frequently disease B—toxemia—follows disease A, rather than the way in which Peters studied the problem, namely, how often disease A—pyelonephritis—occurs in disease B—toxemia. (According to Mr Rulon there are too many variables in Peters's method of approach to warrant conclusions.) As for our data, which indicate an incidence of pyelonephritis in pregnancy of 1 to 3 per cent, an incidence of toxemia of approximately 10 per cent and toxemia following pyelonephritis in pregnancy is 12.5 per cent, Mr Rulon states that if the same ratio held in 500 cases (we have only 72) we should be well justified in stating that

pyelonephritis is not a cause of toxemia of pregnancy.

MIXED INTRACRANIAL GLIOMAS

The Diagnostic and Prognostic Significance of Adequate Histological Examination

DONALD MUNRO, M D , F A C S , JESSE E EDWARDS, M D , and WILLIAM O RUSSELL, M D ,
Boston, Massachusetts

IT IS axiomatic that the accuracy of the diagnosis and prognosis of any neoplastic growth will vary directly with the amount and accuracy of the information available in regard to its histology and its location in the body. Such generalities are particularly applicable to the intracranial neoplasms. There are, to be sure, characteristics peculiar to this particular group of tumors which cause them to differ in detail although not in principle with these statements. For example, the usual intracranial neoplasm does not metastasize by way of the blood or lymph channels, but rather spreads locally either by expansion or by radial invasion. Such tumors, if irremovable, cause death, however, by virtue of the profound alterations produced in general, rather than local, central nervous system physiology. Thus, regardless of its histological character, any type of intracranial tumor can and will prove fatal when inaccessible and if properly placed in relation to the nervous structures around it. One phase of the brain tumor problem and of any attempt to estimate its end-results has to do, therefore, with a demonstration of the exact position of the tumor. This is well recognized and all of the modern advances in the therapy of intracranial tumors have depended, at the last analysis, upon the ability of the surgeon to make previously inaccessible areas accessible.

It is less well appreciated, however, that the histological make-up of the tumor is as important from a diagnostic and therefore prognostic viewpoint as its exact location. A circumscribed cerebellar medulloblastoma may be more accessible than the mural nodule in the upper wall of a large astrocytomatous cyst of the same region. Yet, apparently adequate removal of both will produce a lifetime cure in the latter and a life expectancy of not more than a year in the former. Such a difference in prognosis is demonstrable histologically at the time of operation. The importance of this operative histological study has been minimized by some neurosurgeons just as

the accuracy of so called pre-operative localizing signs has been overemphasized by some neurologists. At the last analysis, the final criteria of diagnosis and therefore removability must wait on exposure and adequate biopsy of the tumor either at operation or at autopsy.

These requirements apply in particular to the gliomas. A long step toward effective understanding of these tumors was taken with the publication of Bailey and Cushing's classification (Table I). Bailey further points out in a later publication that "*each type of glioma is a distinct entity with its own idiosyncrasies* which it is important to recognize. Any attempt to describe 'glioma' as an entity only leads to confusion. *In general the gliomas composed of cells resembling those of the early stages of histogenesis tend to develop more rapidly*." Of the groups that are commonly recognized the *medulloblastoma* and the *glioblastoma multiforme* are tumors that are closest to, and the *astrocytoma* the one that is furthest from the original medullary epithelium. In between these extremes lie, in approximate order of histological youth, the *oligodendrogliomas*, *pinealomas*, *ependymomas*, *polar spongioblastomas*, and *astroblastomas*.

It is obvious that tumors of adjacent cellular age may appear as histological mixtures. There have been expressions in the literature which bear on this point. Penfield has emphasized that the cells of any given glioma are originally derived from one primitive cell. With increasing age, differentiation becomes gradually more and more complete. Theoretically, therefore, it is possible to find cells representing varying phases of this differentiation in any one tumor. He reports that this idea is consistent with actual experience so that, for example, a tumor growing largely as an astrocytoma may contain spongioblasts and astroblasts. Globus (3) and Levine have each observed gliomas in which there was a mixture of cell types throughout the tumor. They are of the opinion that these cell types represent phases of glial development, and they have termed these tumors transitional cell gliomas. Carmichael has indicated

From the Mallory Institute of Pathology and the Neurosurgical Service of the Boston City Hospital Boston, Massachusetts

Fig 1 a, Astrocytoma showing numerous neuroglial fibrils Mallory's phosphotungstic acid hematoxylin stain $\times 745$ b, Fusiform cells arranged in parallel rows No intercellular fibrils This area is typical of a polar spongi-

oblastoma Mallory's phosphotungstic acid hematoxylin stain $\times 745$ c, Glioblastoma multiforme showing two mitoses and a tumor giant cell Mallory's phosphotungstic acid hematoxylin stain $\times 225$

Microscopically this tumor showed two fundamental pictures. The major part was growing as a polar spongioblastoma. There were spindle cells with long, fairly well stained cytoplasmic processes, an occasional mitosis, and no intercellular fibrils. This picture was similar to that seen in Figure 1b of Case 2. In a smaller number of fields the tumor failed to show any regularity and tumor giant cells similar to that in Figure 2c of Case 4 were found. We consider these latter areas characteristic of glioblastoma multiforme.

Four other tumors that contained both glioblastomatous and spongioblastomatous tissue had in one case an additional undifferentiated part that resembled medulloblastomatous tissue and in the 3 other cases additional astrocytomas (twice) and oligodendrogliomatous sections as well.

Case 2 (Nerve, A 36 450) Female, aged 56 years. For 1 month previous to entrance she had complained of increasing weakness and staggering gait, falling to the left, transient diplopia, headache and drowsiness with difficulty in thinking. For a few days before admission, she had been vomiting and had felt weak. She lost 10 to 12 pounds in this month. There had been no injuries or illnesses in the past. General physical examination was negative except for pallor and signs of recent weight loss. She was drowsy and unco-operative. She showed a left hemiparesis including the lower facial region. The deep reflexes were increased on the left. There were bilateral Babinski, Oppenheim, and Gordon signs. There were high choked discs and she was unable to count fingers with the left eye at 3 feet. Her blood pressure was 90/60 millimeters mercury. She had a slight anemia and a positive blood Hinton. Lumbar punc-

ture showed an intracranial pressure of 470 millimeters water with normal dynamics. The cerebrospinal fluid had 51 white blood cells, 10 per cent of which were polymorphonuclears, a total protein of 78 milligrams per cent, and a doubtfully positive Kahn test. Other specimens showed cells as high as 1,300, from 25 to 100 per cent polymorphonuclears and total proteins from 130 to 750 milligrams per cent. She died suddenly and untreated 8 days after admission.

At autopsy the brain weighed 1,270 grams. There was a moderate cerebellar pressure cone with widening and flattening of the cerebral convolutions. In the right cerebral hemisphere, there was a huge tumor mass extending posteriorly from the anterior tip of the right frontal lobe to a level 5 centimeters anterior to the tip of the occipital lobe. Laterally the tumor extended to the surface of the cerebral substance and medially to the lateral border of the right thalamus. The tumor tissue was soft yellowish white and possessed a purplish brown border.

Microscopically some areas of the tumor showed well differentiated cells with prominent intercellular fibrils staining purple with the phosphotungstic acid hematoxylin stain. These areas may be considered characteristic of astrocytoma (Fig 1a). Other areas showed definite spindle-shaped cells whose cytoplasm stained fairly well. There were no intercellular fibrils. In these areas the tumor resembled a polar spongioblastoma (Fig 1b). In other regions were poorly differentiated cells with mitotic figures and tumor giant cells characteristic of glioblastoma multiforme (Fig 1c).

Case 3 (N S 3350, S 39 2799) Male aged 64 years. One year and 10 months before admission this patient complained of substernal burning of 1 month's duration. A diagnosis of cardiospasm was made in another hospital.

Fig. 1. a, Poorly differentiated tumor with rather uniform cellularity and absent giant cells—suggests medulloblastoma. Mallory's phosphotungstic acid hematoxylin stain. $\times 500$. b, Characteristic pattern of polar spongi-

oblastoma. Mallory's phosphotungstic acid hematoxylin stain. $\times 500$. Large immature cells and one tumor giant cell typical of glioblastoma multiforme. Mallory's phosphotungstic acid hematoxylin stain. $\times 500$.

This diagnosis was changed 3 months later to arterio-sclerotic heart disease with coronary insufficiency and angina pectoris. He was given $\frac{1}{2}$ grain of lanolin 4 times daily and was free of symptoms 1 month later. Vision at that time was 20/30 corrected. His chief complaint was of circumferential sensation over the right temple. He was sent to the Boston City Hospital for the first time 6 months before his final admission. He complained of bilateral supra-orbital pain, formation over the scalp, and sensation of peculiar odors. Examination showed papilledema of 3 diopters but no localizing signs. A diagnosis of brain tumor—suspect of metastatic origin—was made. A month later his memory began to fail and he developed personality changes. He refused to permit adequate investigation at that time. On his final admission he was in deep coma. There was no history of injury or disease except as noted. On physical examination he showed slightly enlarged heart, generally depressed tendon reflexes, left hemiparesis, and choking of 4 diopters. He responded only to painful stimuli. His blood pressure was not recorded. Lumbar puncture showed an intracranial pressure of 40 millimeters of water. The cerebrospinal fluid was clear and colorless without cells and with total protein of 3 milligrams per cent. A cerebrogram as done the day after admission. It showed displacement of the anterior horns and the third ventricle to the left with dilatation on the left. The right ventricle was not entered with the needle, being overlaid by cyst which then as visible as separate structure in the right temporo-occipital region. The cyst fluid had total protein of 530 milligrams per cent and the left ventricular fluid one of 47 milligrams per cent. A low right parieto-occipital craniotomy was performed. This revealed an extensive infiltrating tumor which lay astride the Sylvian fissure. On section, the tumor was found to be tough and had the appearance of meningioma. A biopsy was done. The diagnosis from this tissue as reported as malignant metastatic tumor probably carcinoma, and with many mitoses. No further attempt at removal was made. The dura was closed tightly and the bone flap replaced. The patient did not regain consciousness and died 24 hours later. No autopsy was permitted.

Later and more detailed study of the biopsied tissue changed the original diagnosis. Microscopically the tumor showed large areas in which the cells were well differentiated. The cytoplasm stained poorly however and the nuclei varied in shape from ovoid to spherical. Numerous intercellular neuroglial fibers were present. In such

areas the tumor was considered to be growing as an astrocytoma, the tissue being similar to that shown in Figure 7a of Case 9. In other areas the picture was that of a polar spongioblastoma. The tumor cells were fusiform and had cytoplasm that stained fairly well. No intercellular fibrils were present. The appearance here was similar to that shown in Figure 1b, Case 2. In still other fields the cells were poorly differentiated, with tumor giant cells and moderate numbers of mitoses. We consider this appearance characteristic of glioblastoma multiforme shown in Figure 5c, Case 7.

CASE 4 (N. S. 3035, A 38451) Male, aged 64 years. Three months before entrance this patient began to have severe throbbing, generalized headaches, shortly followed by repeated grand mal type of convulsive seizures. He had had no such during this period. The cells before admission his left side became weak. There was no other significant family or past history. On admission he was lethargic and somewhat like an evident memory defect. Physical examination as noncontributory except for the fact that he kept his head rotated to the right and that he had an enlarged bony prostate. His blood pressure was 40/60 millimeters of mercury. He showed left hemiparesis and some hyperreflexia. His position Babinski, Gordon and Oppenheim signs, the last being present on his right as well. The right disc was choked and the left could not be seen on account of lenticular opacities. There was negative blood Hinton. Lumbar puncture showed an intracranial pressure of 350 millimeters of water, like normal dynamics. The cerebrospinal fluid was clear colorless, without cells and had total protein of 63 milligrams per cent and gold sol of 32 units. Six days after admission, a cerebrogram was done. It showed displacement of the ventricles to the left and in addition shadow which looked like separate lesion projecting into the lateral ventricle on the left. Fluid with total protein of 6300 milligrams per cent as obtained from cyst on the right at this time. The left ventricular fluid had 7 milligrams per cent of protein. A right posterior parietal craniotomy was done 4 days later. A subcortical scarlet tumor was found in the temporo-parietal region. The bony flap was reported as having been identified as an astrocytoma. Excision was out of the question, on account of the tumor's size, so after providing small decompression, the rest of the dura was closed and the bone flap replaced. The patient died 48 hours later without regaining consciousness.

Fig 3 a Typical arrangement of cells of a polar spongioblastoma Phloxine methylene blue stain $\times 745$ b, Rather uniform cellularity with prominent cell margins and little intercellular substance Strongly suggestive of

oligodendroglioma Phloxine methylene blue stain $\times 745$ c, Tumor giant cell and undifferentiated cells characteristic of glioblastoma multiforme Phloxine methylene blue stain $\times 745$

At autopsy the brain showed diffuse widening and flattening of the convolutions. In the right occipital pole there was a well circumscribed firm tumor measuring 4.0 centimeters in diameter. The center of the mass showed numerous cyst like spaces measuring up to 2.0 millimeters in diameter and containing a light greenish yellow coagulum. In addition, in the superior portion of the right parietal lobe, there was a moderately firm, well circumscribed tumor measuring 1.3 centimeters in diameter.

Sections taken from the two tumors exhibited three types of glioma. In some fields the cells were fusiform with polar cytoplasmic processes. There were no intercellular fibrils. We may consider these areas as exhibiting the characteristics of a polar spongioblastoma (Fig 2b). Another area exhibited poorly differentiated tumor cells whose cytoplasm stained very faintly. The nuclei were vesicular with prominent nucleoli. The nuclear shape varied from round to oval. There were no giant cells. Although for the greater part there was no characteristic arrangement, there was a suggestion of pseudo-rosette formation in a few instances. Intercellular fibrils were absent. We may consider this part of the tumor as a medulloblastoma (Fig 2a). Associated with the regions appearing as polar spongioblastoma there were some areas showing larger cells than in either of the above. These cells showed poor differentiation and in some instances true tumor giant cells were encountered. We may consider these latter fields as exhibiting the criteria of glioblastoma multiforme (Fig 2c).

CASE 5 (N S 3273, A-30-444) Male, aged 44 years. This patient was known to have been a chronic alcoholic for a number of years, and he was believed to have had weakness of his legs for 5 years but more detailed information was lacking. He may have had a head injury 9 months previous to admission. Three months before admission, he was taken to another hospital during an alcoholic spree. While there, he developed bronchopneumonia and in the course of his stay was found to have had "marked generalized hyperreflexia, dysmetria, ataxia, sluggish pupils and bilateral choked discs." A lumbar puncture at that time showed an intracranial pressure of 500 milligrams of water. The cerebrospinal fluid was found to have had a total protein of 80 milligrams per cent. On this last admission, he was disoriented and ataxic and had noticeable weakness of his legs. Physical examination demonstrated atrophy of the muscles of his left arm, both shoulders, and both legs. His blood pressure was not recorded. He had bilateral high choked discs, nystagmus, dysmetria, and ataxia. He staggered and fell toward the left. There was marked weakness of the left hand. He had hyperactive tendon jerks, bilateral ankle clonus, and Babinski signs. The Weber test was lateralized to the right. Two days after admission, a ventricular estimation demonstrated a marked bilateral hydrocephalus with 10 and 9 milligrams per cent of protein in the right and left ventricular fluids, respectively. No air was put in the ventricles. Immediately following this procedure, a suboccipital craniotomy was started. It had to be abandoned after removal of the bone on account of excessive bleeding. The patient died without regaining consciousness about 8 hours later.

At autopsy, in addition to an intraventricular hemorrhage and bilateral bronchopneumonia, a tumor of the cerebellum and brain stem was found. The brain weighed 1,350 grams. A moderate cerebellar pressure cone was found. There was a moderately firm tumor lying beneath the pia arachnoid and involving the right cerebellar tonsil, brachium pontis, and the restiform body. The neoplasm measured 4 by 2 by

Fig. 4. a. Gland like arrangement of cells with bipolarity. This is characteristic of an ependymoma. Mallory's phosphotungstic acid hematoxylin stain. $\times 780$. b. Poorly differentiated cells with tumor giant cells. This is indicative of glioblastoma multiforme. Mallory's phosphotungstic acid hematoxylin stain. $\times 740$.

centimeters and on cut section revealed nodular surface which for the greater part showed light yellowish gray color in which are smaller light brown areas measuring up to .5 centimeter in diameter. There is moderate dilatation of the lateral ventricles.

Microscopically the tumor exhibited considerable variation in appearance from field to field. In some areas the tumor had the appearance of a polar spongioblastoma, the cells being of moderate size and spindle shaped (Fig. 3a). Intercellular fibrils were absent. In still other fields there were sheets of tumor cells with prominent cell margins which gave them the appearance of an oligodendroglioma (Fig. 3b). In other areas there was the haphazard cellular arrangement with tumor giant cells that is indicative of glioblastoma multiforme (Fig. 3c).

Four other tumors had in addition to the glioblastomatous, ependymomatous theme (twice) and astroblastomatous or astrocytomatous sections once each.

CASE 6 (N 5 586, S-30-3094). Male, aged 3. This patient as child until January, 1937. At that time he suddenly developed diplopia. Four months later he had severe frontal headache accompanied by nausea and vomiting. Four months later he, as first admitted to the hospital, had had no previous history of injury or other significant illness. Glasses had relieved his headaches before admission but transitory attacks of diplopia persisted. Physical examination revealed child developed and well labeled boy of 3 years. His genitalia are small and the

right testicle is undescended. He is co-operative and oriented conscious and rational. There is edema of the left external rectus muscle and of the left side of the face of central type. The discs are markedly choked and exudate as present. There is right homonymous hemianopsia. His tongue deviated to the right. The tendon reflexes are all markedly depressed or absent. There are bilateral Babinski and Chaddock signs. His blood pressure is not recorded. His pulse, temperature and respirations are all normal. There is noticeable clumsiness of both hands. A lumbar puncture showed an intra cranial pressure of 350 milligrams of water. The cerebrospinal fluid is clear and colorless with total protein of 45 milligrams per cent. The rest of the laboratory tests are normal. A diagnosis as made of left cerebral tumor and left posterior parietal craniotomy as performed. A large cyst as tapped in the lower parietal area. This as opened and drained after which large bluish red, vascular and cellular tumor as found on its medial side. A piece as removed and examined microscopically. As result, it as reported to be an ependymoma. Further exploration demonstrated that the tumor had invaded the skull and partly filled the cavity of the lateral ventricle. It as very vascular and so as left intact except for the biopsy. A decompression as provided, and the bone flap replaced. After stormy convalescence he as discharged to his home. At that time he as aphasic, had bilateral motor weakness and unsteady gait. The choking had disappeared and the visual fields, especially that on the left, are noticeably improved.

For year and one half he continued to improve and became practically normally active. At the end of that time he had his first convulsions (attack) eight months later having completed at home the work done in public schools by boy of his age, he again had diplopia and early choking of his discs was again discerned for the first time.

Fig 5 a, Large spindle cells arranged in a palisade formation with coarse intercellular fibrils. Suggestive of ependymoma. Mallory's phosphotungstic acid hematoxylin stain $\times 745$. b, Numerous intraprotoplasmic and blepharoplastin granules. These cells establish the diagnosis of

ependymoma. Mallory's phosphotungstic acid hematoxylin stain $\times 1490$. c, Haphazard cellular arrangement with tumor giant cells. This is characteristic of glioblastoma multiforme. Mallory's phosphotungstic acid hematoxylin stain $\times 745$.

He was given x ray therapy and 2 months later was improved. One month after completion of a series of 20 treatments, he was readmitted to the hospital because of increasing drowsiness to coma for the previous 24 hours. This was 2 years and 9 months after the onset of his symptoms and 2 years and 3 months after his operation. He had all the signs of increased intracranial pressure. The right ventricle and the cyst on the left were emptied through the old trephine holes as an emergency measure and 19 days later the old craniotomy wound was reopened. A radical resection of the tumor that now filled the ventricle and invaded large areas of the parietal and temporal lobes was done. Many cysts were encountered, much tissue was soft enough to suck out, and much was very firm and fibrous and had to be removed by sharp dissection. He had a stormy convalescence with severe headaches, a right hemiparesis, and profound aphasia. During his hospital stay he was given another series of x ray treatments and eventually was sent home 2 months after admission able to speak normally, without choked discs, and active all day with the aid of a cane and an orthopedic brace to control his foot drop. He still had a right homonymous hemianopsia. He has continued to improve during the succeeding 6 months to date.

A complete histological study was carried out on the tissue that was removed at the last operation. It was composed, in gross, of many pieces of friable gray tissue, the aggregate mass measuring 3.0 cm in diameter.

Microscopically, some regions of the tumor showed fairly well differentiated cells. In some instances these were columnar in shape and assumed gland-like formation. The cytoplasm beneath the margin of the gland-like spaces contained moderate numbers of diaphoroplastin granules (Fig 4a). These areas were considered charac-

teristic of ependymoma. In other areas the tumor appeared as a glioblastoma multiforme with lack of cell uniformity and the presence of multinucleated tumor giant cells (Fig 4b).

CASE 7 (N S 2950, S 38 1696). Male, aged 53 years. This patient had been entirely well up to 2 weeks before his admission. At that time he had "bumped his head" without unconsciousness or other immediate symptoms. Frontal headaches developed for which he consulted his local doctor and was told that he had "sinusitis." For the week previous to admission he was unable to read and was "out of his mind." On admission he was completely aphasic, disoriented, and confused but co-operative. Physical examination showed moderate arteriosclerosis, bilateral high choked discs, right homonymous hemianopsia with sparing of the maculae, dilated fixed pupils, alexia, and partial sensory and motor aphasia. There was no astereognosis. The patient was right handed. The tendon reflexes were within normal limits, and there were no abnormal reflexes. He had a high intracranial pressure (230 mm water) with cerebrospinal fluid that was clear, colorless, without cells, and with a total protein of 70 milligrams per cent. Serological tests were all negative. His blood pressure was 128/70 millimeters of mercury. Two weeks after admission a left temporoparietal craniotomy was performed. A large soft infiltrating cystic tumor of the temporal lobe was widely removed. Microscopic diagnosis at the time of the operation was glioblastoma multiforme. A decompression was provided, and the bone flap was replaced. He made a satisfactory convalescence and returned home 2 weeks after the operation with a normal intracranial pressure but with all his other symptoms and signs just as they were before operation. During the succeeding 6 months at home he gradually went down hill and after a week of unconsciousness, died 8 months after he had noticed his first symptom. There was no autopsy.

Fig. 6. a. Pyramidal shaped cells with sucker feet attached to the all of blood vessel. This is characteristic of astroblastoma. Mallory's phosphotungstic acid hematoxylin stain. $\times 555$ b. Haphazard cellular arrangement like tumor giant cell. This is characteristic of glioblastoma multiforme. Mallory's phosphotungstic acid hematoxylin stain. $\times 555$

A complete histological examination as carried out on the tissue removed at operation. This as in the form of several fragments of firm to gritty gray like tissue, the largest measuring 1 centimeter in diameter the smallest 0.4 centimeters.

In some microscopic fields the tumor cells were elongated, fleshy and arranged in palisade formation. There were coarse intercellular fibrils (Fig. 5a). Some cells exhibited numerous blepharoplast granules in their cytoplasm thus establishing the diagnosis of ependymoma (Fig. 5b). In other fields there was no orderly cellular arrangement nor any intercellular fibrils. Mitotic figures were numerous and tumor giant cells were present in moderate numbers. We classify the tumor in these fields as glioblastoma multiforme (Fig. 5c).

CASE 8 (N. S. 3052, 5-35-700). Female aged 39 years. For 5 months before admission, this patient had been having left frontal headaches and increasing somnolence. At the time she first noted these symptoms, she was 8 months pregnant. 7 months before admission, she fell. Following that she began to act abnormally, talked out of one side of her mouth, and developed weakness of her left hand. Having always been left-handed she now began to use her right hand almost exclusively. Her left leg, face, and shoulder progressively became weaker until she had complete left hemiplegia. For 1 month before admission, she had moderate aphasia and for week she had been vomiting and complained of loss of sight in her left eye. On admission, she was stuporous and restless. She had had no significant previous illnesses or injuries. Physical examination demonstrated that she as 8 months pregnant, had left hemiplegia, arteriosclerosis on the left and aphasia. Her blood pressure as not recorded. At lumbar puncture she was shown to have an intracranial pressure of 30 millimeters of air. The cerebrospinal fluid as clear colorless, without cells and had total protein of 86 milligrams per cent. Blood and cerebrospinal fluid Wassermann and Hinton test are negative. She showed trace of sugar but no albumin in its urine examination. She had secondary aneuph. T cells after admission she as delivered of 1 lb. baby by cesarean section. The baby however died in few days of hemorrhagic disease of the newborn. The mother convalesced as uneventful.

Three weeks after the cesarean section, craniogram showed the right lateral ventricle to be compressed, the both ventricles displaced to the left and large cyst in the middle region of the right cerebral hemisphere. The left ventricular fluid had total protein of milligrams per cent and the cyst one of 4,660 milligrams per cent. The following day right posterior parietotemporal craniotomy was done. The subcortical cyst as opened just above the supramarginal gyrus, and tumor tissue as demonstrated posterior and superior to it. Microscopic examination of biopsied specimen of this tissue as reported as showing rapidly growing astrocytoma. This cyst, all as destroyed and small amount of tumor removed. It proved to be impossible to replace the bone flap, so it as sacrificed, the dura being closed except on the posterior inferior margin. After stormy convalescence complicated by cerebrospinal fluid fistula through the scalp wound, she got up and about the 3rd day and as allowed to return home 3 months after admission. There as considerable bulging of the decompressed area.

For 3 months she as comfortable and moderately active about her home. She had no symptoms and as bothered only by the increasing size of the decompression. At this time she began to be disabled by as increasing hemiplegia and hemianopsia. Her blood pressure as 140/84 millimeters of mercury. She as readmitted for possible re-operation. Tissue as attempted but had to be abandoned on account of excess bleeding. The wound failed to heal, fungus developed, she became rather irrational and confused, and eventually died 4 months later, year and 3 months after her first symptoms and year and 3 months after her first operation. There as no autopsy.

The tissue removed at the first operation was subjected to a later more detailed study. It was an egg shaped mass measuring 5.5 by 3 by 2.5 centimeters. The tissue cut with moderate resistance and the cut surface presented alternating areas of white, lemon yellow and black.

Microscopically the tumor was largely composed of cells whose nuclei are fairly vesicular and cytoplasm indistinct. Intercellular fibrils were absent. About blood vessels the tumor cells appeared fusiform with fairly well defined sucker feet attached to the endothelium. This part of the

Fig 7 a, Well differentiated cells with numerous neuroglial fibrils. This is characteristic of an astrocytoma. Hematoxylin and eosin stain $\times 745$. b, Huge giant cells somewhat resembling foreign body giant cells. These

probably represent multinucleated astrocytes. Hematoxylin and eosin stain $\times 745$. c, Large tumor giant cell establishing the diagnosis of glioblastoma multiforme. Hematoxylin and eosin stain $\times 745$.

tumor was considered to be an astroblastoma (Fig 6a). In other scattered fields mitotic figures were fairly numerous and occasional tumor giant cells were found. This tissue we consider typical of glioblastoma multiforme (Fig 6b).

CASE 9 (Private, S-38 1967). Male, aged 67 years. This patient had been well and active until 9 months before admission. At that time he was injured in an automobile accident having been struck on the right temple. He was unconscious for a short period. He remained active in business for 7 months after although it was noted that during that time he became more and more irritable and forgetful and was easily depressed and fatigued. At this time he first complained of "stiffness" of the left hand and arm to which a sense of numbness and awkwardness was added after he had been curling on one occasion. Ten days before admission he had a convulsive seizure involving his left hand, arm and face without loss of consciousness. This was repeated at intervals until admission. The attacks were preceded by paresthesias in the same distribution. Physical examination showed normal eye grounds, obesity, arteriosclerosis and a flaccid paralysis of the left hand and arm with absent tendon reflexes. There were increased knee and ankle jerks with the left greater than the right, slight bilateral ankle clonus and no abnormal reflexes. There was a left hypesthesia. His heart was enlarged to the left and there were some moist rales at the bases of his lungs. His blood pressure was 180/100 millimeters of mercury. At lumbar puncture an intracranial pressure of 100 millimeters of water was demonstrated. The cerebrospinal fluid was clear, colorless, had 3 lymphocytes and a total protein of 47 milligrams per cent. Roentgenograms of the skull showed the pineal gland in normal position. A diagnosis of cerebral subdural hematoma was suspected and 4 weeks after admission a right craniotemporal exploratory trephination was done. It was noted that the temporal lobe was softer to palpation than the rest of the brain and after removal of about 30 centimeters of fluid

that was thought to be but could not be proved to be subdural fluid the brain fell away about $\frac{1}{4}$ inch from the under surface of the dura. The dura was left open and the wound was closed about a drain which was removed 24 hours later. The fluid collected at operation proved to have a total protein of 45 milligrams per cent. The operation made no change in his symptoms or signs. He gradually grew weaker and more confused, had an occasional generalized convulsive seizure and died 5 weeks after operation after a short period of unconsciousness.

At autopsy, the brain showed an extensively infiltrating tumor involving the right frontal and parietal lobes.

The microscopic sections showed considerable variation in appearance with the tumor growing fundamentally as an astrocytoma and as a glioblastoma multiforme. In some areas the cells were well differentiated although their cytoplasm stained poorly if at all, and there was an abundance of intercellular fibrillar substance (Fig 7a). A number of fields showed numerous giant cells which appeared to be of two types, one of which showed considerable cytoplasm with a rim of well differentiated and relatively small nuclei. These cells had some similarity to foreign body giant cells as seen outside the central nervous system and probably represented the giant astrocytes described by Penfield (Fig 7b). These findings were considered typical of an astrocytoma. Other giant cells showed a relatively small amount of cytoplasm and large irregular nuclei, a picture characteristic of tumor giant cells (Fig 7c). These cells were associated with a moderate number of mitoses. This picture was consistent with the diagnosis of glioblastoma multiforme.

If Bailey and Cushing's theory of progressive cellular age in the development of gliomas is correct, it will be evident that the combinations here described not only bring together in one mass cells at opposite ends of a single family tree, but also cells from two entirely discreet families. No explanation is offered to account for this bizarre cellular grouping. It is merely recorded in the hope and expectation that it, together with other similar observations will eventually help to clarify the glioma problem.

In the meantime and from the clinical point of view the malignancy of glioblastomas, the benignancy of astrocytomas, and the appropriate varying degrees of malignancy of the intervening tumors must be accepted as the present foundation on which to build surgical therapy. Even this statement must be regarded as only temporary, however. Scherer, in an article entitled "The Forms of Growth in Gliomas and Their Practical Significance" presents conflicting evidence which if confirmed, may be taken as demonstrating that a considerable percentage of glioblastomas are therapeutically favorable and that all astrocytomas are invariably therapeutically unfavorable tumors. Lacking such confirmation, it is better for the present to adhere to the more orthodox and older beliefs. From this point of view the potential inaccuracy of the biopsy diagnosis made at the time of the operation in this series is striking. There was a failure to identify histologically at this time the presence of the most unfavorable type of tumor cell in 4 of 6 cases, and in only 1 case was the co-existence of the more benign cells accurately recognized. In 2 other instances, the presence of a tumor was not even suspected even though one patient was explored in the attempt to make a diagnosis. In the remaining patient, a pre-operative diagnosis of neoplasm was made but the tumor could not be exposed on account of the man's condition.

Little help in detecting the type of tumor was had from the history and examination. Of the two the history was probably of greatest significance. The one cerebellar tumor caused recognizable symptoms for 5 years before the patient consulted physician about them. However the patient suffered from chronic alcoholism for which he was hospitalized several times. At his final admission he was in coma and the history was obtainable only from friends and previous hospital records. In no other instance did this period exceed 6 months and in one the patient himself repeatedly stated before and after the diagnosis had been made that his symptoms preceded his hospitalization by only 2 weeks. In 1 case hos-

pitalization was brought about because of an acute exacerbation of previously negligible symptoms by pregnancy. A living 8 months baby was delivered by cesarean section but it died of hemorrhagic disease in a few days. One month later subtotal resection of mother's tumor was done.

The location of the cerebral tumors was also without diagnostic or prognostic significance.

The postoperative survival period was of no significance. It was conditioned by such uncontrollable factors as previous alcoholism, inadequate food, pregnancy, syphilis, age, misleading history, the presence of a cyst in the tumor and so forth. The only patient with a significant survival period is one that had a combined glioblastoma and ependymoma which was partly intraventricular. He is still living at the age of 16, 3 years after his first operation. One of the 2 correctly diagnosed cases, as far as the glioblastomatous part went, lived 6 months and the other 9 days after operation. Only a small biopsy was done in the latter. One patient with a tumor that was partly glioblastomatous and partly astroblastomatous lived 14 months and another with a tumor that was partly astrocytomatous lived 5 weeks. The former had a subtotal resection and removal of the bone flap at her first operation followed by repeatedappings of a cyst and 2 secondary operations. The latter did not even have his tumor exposed. Four tumors were cystic in part, the rest being completely solid. Two cases died because of peripheral circulatory failure 48 hours and 14 months after the first operation. One died because of a ventricular hemorrhage 12 hours after operation, in one the cause of death was not determined and the remaining patients died of massive cerebral edema with a cerebellar cone from a few hours to 9 days after operation.

Failure to make a correct histological diagnosis of the tumor at the time of operation was due to one chief factor. In this connection, it is obvious that those cases in which the tumor was not seen because of no or inadequate operative exposure can be eliminated. With these eliminated there are 31 more which were classified from material removed at operation only and 3 in which postmortem studies were made in addition. Regardless of anything else the important datum to obtain at the earliest possible moment about any intracranial tumor is whether or not it is wholly or partly made up of malignant glioblastomatous or medulloblastomatous tissue. As a corollary to this, care must be taken, of course not to confuse the giant astrocytes described by Penfield as occurring in astrocytomas (Fig. 7b) with the true tumor giant

cells that characterize the glioblastomas. Thus, the ultimate measure of success that attends any attempt at classifying histologically a given tumor rests on the ability of the pathologist to recognize, while the operative field is exposed, the presence of either one of these 2 cell groups regardless of whether or not any other less malignant cell group is identified at the same time. In the 6 cases in which surgically removed tissue was available, this requirement was met twice. Immediate diagnoses were made from tissue obtained by small biopsies in 3 and by subtotal excisions in 3. Glioblastomatous tissue was recognized once in each group. It is fair to conclude, despite the small size of the group and because of a 66 per cent error, that accurate operative histology requires more tissue than is obtainable from any removal smaller than that of a wide spread excision. All these first diagnoses (made while the patient was being operated upon) were made on fresh tissue examined either after supravital staining of a smear or after frozen section, or both. That the dual nature of these tumors was not recognized at this time was due partly to the concentration of the pathologist on making a single definite cellular diagnosis but chiefly to the small amount of tissue that was provided him. It was not until after more material was obtained by autopsy or a more prolonged study of a greater number of fixed sections made that the multiplicity of types was recognized. It seems reasonable to conclude therefore, that the accuracy of the histological classification of an intracranial glioma, even if not extended beyond the point where the only requirement shall be a certain recognition of the presence of glioblastomatous and medulloblastomatous tissues, increases directly with the amount of tumor tissue made available by the surgeon and studied by the pathologist.

SUMMARY

The classification of intracranial gliomatous tumors as proposed by Bailey and Cushing cannot be considered satisfactory or final at this time. If adhered to, it has been found possible to demonstrate in individual tumors cells from either extreme of a given family tree or from different families altogether. In the absence of any classification as good however, it is preferable to use it at this time and, as a result, to consider the glioblastoma and medulloblastoma as histologically the most malignant and unfavorable types and the astrocytoma and ependymoma as the most benign and favorable types of the common intracranial gliomas. On that basis, it must be conceded that the therapy and prognosis of any given

intracranial glioma will depend on the ability of the pathologist to recognize in biopsied specimens and during the operative procedure, the presence of glioblastomatous or medulloblastomatous tissue, more accurate classification being reserved for later study. Furthermore, it appears probable that any intracranial glioma that contains either of these two cell groups has, for practical purposes, a life expectancy of about a year and that the operative risks must be assayed accordingly. Such risks should include not only the chances of death on the table but the even more important chances of life with complete disablement. The accuracy of the pathologist's diagnosis and therefore the amount and efficiency of the surgeon's therapy varies directly with the amount of tumor tissue available to and studied by the former at the time of the operation.

CONCLUSIONS

About 11 per cent of intracranial gliomatous tumors are of truly mixed type.

A patient with an intracranial gliomatous tumor, as far as we know now, that contains either glioblastomatous or medulloblastomatous tissue will have, with only rare exceptions, a life expectancy of not more than about 1 year.

Surgeons should not expect and pathologists should not give an opinion as to the degree of malignancy of a given intracranial glioma without the proviso that its accuracy varies directly with the amount of tissue provided by the one and studied by the other.

Surgical therapy of intracranial gliomatous tumors should be conditioned as much by the demonstration by the pathologist during operation, of glioblastomatous and medulloblastomatous tissue, as by the accessibility of the tumor that is to be removed.

We wish to thank Drs. Leslie S. Jolliffe and G. Kenneth Mallory, both of the Mallory Institute of Pathology of the Boston City Hospital, for preparing the photomicrographs.

JUVENILE KYPHOSIS

JOHN T. HODGEN, M.D., F.A.C.S., and CHARLES H. FRANTZ, M.D., F.A.C.S.
Grand Rapids, Michigan

THE orthopedist constantly sees children with rounded shoulders and poor posture. Quite often a patient is presented by the parent seeking advice for one of two reasons—posture or pain and fatigue. Ache and fatigue in children between the ages of 10 and 17 years, when present in the dorsal spine, demand careful investigation. For a number of years the hollow-rounded back of adolescents has interested us.

The clinical condition of juvenile kyphosis is not as rare a disease as formerly thought. In the last two decades the literature has grown to quite a volume, the majority of contributions having appeared in foreign publications.

Schanz first suspected that posterior curvature developing in children did not wholly arise from poor posture in school but had a more serious background. He believed the kyphosis of adolescents was the result of heavy work and unusual demands on the back. Scheurmann, in 1921, described the term *kyphosis dorsalis juvenilis*, publishing his clinical and roentgen interpretations of the irregular outlines of the vertebral bodies. Schmorl, in numerous publications of his anatomical and pathological studies, has given us his conception of the vertebral changes. Haas in the past year has added pertinent studies in regard to growth of the vertebral column and epiphyseal changes resulting from injury.

For the past 6 years particular attention has been paid to children with dorsal back pain and kyphosis. They have been followed carefully and the treatment has been supervised as closely as possible under the orthopedic department.

It is our purpose in this presentation to review briefly the clinical picture of juvenile kyphosis, speculations as to etiology, pathology, and treatment with a few personal additions in the management, which we believe have been an aid in handling these children.

ETIOLOGY AND INCIDENCE

Many hypotheses regarding etiology have been advanced, what the true etiological factors are however is impossible to state definitely. The problem of balance between the capacity of the spine and functional demand is an important factor in each individual case. The use of the

term "functional demand" is based on the evaluation of physical demands made on the individual in relation to the economic status of the home, number of children in the family, rural or urban environment, physical work, labor laws, and educational demands. The capacity of the spine implies tolerance to physical exertion at any stage in its development and must include the factors of growth, diet, and protoplasm.

From a clinical standpoint four possibilities present themselves: (1) abnormal functional demand plus normal back—juvenile kyphosis; (2) abnormal functional demand plus abnormal back—juvenile kyphosis; (3) normal functional demand plus normal back—0; (4) normal functional demand plus abnormal back—juvenile kyphosis.

Statements one and two seem self-explanatory. If one accepts developmental defects such as malformations of the vertebral body, malposition of notochordal structures, and endocrine disturbances, Schmorl is of the opinion that there are abnormalities not evident particularly in the cartilaginous stage of development which, under stress and strain of greater functional demand, become clinically pathological. Statement three must be considered as a possibility. However, with no abnormal elements present a pathological picture can hardly be expected to develop. Statement four is a combination of factors which we believe may produce the clinical entity. This patient is a small part of the group and usually presents no pain, ache, or fatigue. Posture only is poor. These children appear in the non-indigent class and no abnormal demands could be determined during the daily routine.

From a study of 50 cases, the most frequent age of onset was found to be between 10 and 11 years (Fig. 1). Contrary to some observers, the incidence was found to be greater in girls (78 per cent). This observation coincides with the pre-dominance of females as recorded by Burns and Ellis in the Royal National Orthopedic Hospital and with the figures of Schuklbach of Leipzig. The incidence peak is highest earlier in girls, being reached at 11 years and in boys at 14 years. In appraising the body types of these children it was found that the tall, thin child of the asthenic constitution appeared twice as frequent as the short, stocky, pyknic individual (Fig. 2). The

Fig 1 Incidence

majority of patients presented themselves under 6 months after the onset of symptoms—smaller groups sought advice from a year to 18 months following initial symptoms (Fig 3). From the time element it would appear that the symptomatology in these children is not alarming nor is it of a severe nature in regard to pain or acute discomfort.

PATHOLOGY

Prior to anatomical investigations, the changes of the vertebral column in juvenile kyphosis were largely interpreted from the roentgenogram. Scheurmann in 1921 described the changes in adolescent spines from the roentgenogram, pointing out the increased dorsal curve and wedging of the body. Shanz before him speculated on the factors back of these changes early in 1907.

Numerous publications by Frejka, Mau, Calve and Galland, and Meyer described the clinical picture and development of deformity. All these authors turned in part to Schmorl's anatomical dissections and Scheurmann's interpretations for explanation of the changes occurring within the disc and vertebral body. These investigators carried out extensive studies of the spine and came to definite conclusions as to the development of the pathological picture. Schmorl's theory propounds the herniation of the nucleus pulposus into the vertebral body causing reactive changes and cessation of bone growth. Scheurmann believed the primary change not a nuclear herniation but erosion of the anterior corners of the bodies, and also states that nuclear herniations are not always present. Cloward and Bucy reviewed cases of extradural cysts of the cord in which kyphosis was present. These cases occurred in children, and so consistent were the findings that coincidence appeared out of the question. The explanations

Fig 2 Constitutional type

offered in relationship of the cysts to development of kyphosis may spread some light for future investigation. Their theory states that venous stasis and congestion within the ventral body may be a contributing factor. All these writers have attempted reasonable explanations for the changes, but there still remains much controversy. One cannot possibly outline the various individual conceptions in this short review, however, the general conception of the changes can be sketched here.

Anatomically, the intervertebral disc consists of three distinct parts, the annulus fibrosa, the nucleus pulposus, and the two cartilaginous end plates which form the inferior and superior coats of the disc.

The annulus is a fine fibrous network running in oblique planes covering the anterior lateral and posterior borders of the discs. It completely encircles the intervertebral disc substance and is

Fig 3 Duration symptoms prior to treatment

Fig. 4. Symptoms and signs.

attached more loosely in the dorsal or posterior aspect. The peripheral edges of the annulus send fibers deep into the marginal ledges of the vertebral body. The fibrous networks of the annulus pass gradually centralward becoming less dense and less compact, gradually merging into the nucleus pulposus which is partly myxomatous and partly fibrillar. In youth the pressure within this structure is greater than in the aged. Petter found that, on removal from the body, the intervertebral disc expands and a pressure of some 30 pounds is necessary to reduce this expansion. Evidently this pressure is due in part to water content. In the youth there exists 80 parts of fluid as in contrast to the aged where only 60 parts fluid is present.

The cartilage end plates are thin rigid structures of hyaline cartilage forming the superior and inferior surfaces of the disc. They do not reach the outer visible margin of the disc but end on the inner marginal ledge of the coram, which will be mentioned below.

The tension within the nucleus is maintained by the lamina and cartilage end plates. Schmorl removed a bony vertebral body from the disc being careful not to injure the cartilaginous end plate and found that the tension within the intervertebral disc did not change. He concluded, therefore, that the cartilaginous end plates must be an important factor in maintaining tension. Evidently then the cartilage plate is as intimate with the disc as with the vertebral body.

If for some reason the resistance of the cartilaginous end plate is below normal, changes in tension may occur by herniation of nucleus tissue through small splits in this end plate. Whether these fissures or interstices develop from strain or trauma, or weakened areas exist as the result of involuted nutrient vessels from an earlier age, cannot definitely be stated. The abnormalities may remain within the bounds of clinical normalcy

and assume a pathological character only under the stress and strain of increased functional demand on the disc. It is from this basis that we mentioned the four statements or combinations possible in developing the clinical entity.

It is believed that under increased demand zigzag fissures appear in the cartilaginous plates, allowing nuclear material to herniate into the spongiosa of the vertebral body. The pressure of the nuclear substance further tears and enlarges the fissures allowing a greater mass to come through. Reactive changes develop around these cartilage nodules in the spongiosa of the vertebral body. By release of tension the width of the intervertebral disc is lessened and the cartilaginous plates approach each other. In areas in which the perforations occur through the bony end plates of the vertebral body the cartilage proliferation zone is destroyed and bone growth ceases. This is the case at the ventral or anterior portion of the vertebral body when greater pressure is exerted.

The delay in growth is shown as narrowing of the anterior body producing the picture of wedging. Defects in the ossification are seen along with irregular broadening of the cartilaginous proliferation zone.

Schmorl apparently objects to the term vertebral epiphysis as used by Scheurmann in designating the ossification line as an epiphyseal line. He stated and was supported by Virchow that the so called secondary epiphysis is not a growth epiphysis in the same sense as long bone. The vertebral body develops by endochondral bone growth on the spongiosa side of the cartilage end plates. One may be justified in speaking of this as a growth zone and not an epiphysis, thus, discarding the term vertebral epiphysitis. Haas, however, in experimentation on dogs concluded that the growth in length of vertebrae occurs in manner similar to growth in length of long bones, a proliferation at the cartilage end plate with no interstitial growth within the body. It produced both kyphosis and scoliosis by injuring these plates surgically. These variants in conception of growth do not change the ultimate result. The nuclear substance under pressure, whether destroying the cartilage proliferation zone of Schmorl or the cartilaginous epiphyseal cells according to Haas, interrupts the growth anteriorly to produce wedging or lateral changes may produce a scoliosis.

Frejka seems to stress the possibility of nasal obstruction playing an important rôle in the development of kyphosis. Children with large adenoids and tonsils breathe through the mouth, such respiration is shallow and there is a more or less constant condition of expiration in the thorax. A

constant condition of this description causes a change in posture and in the general form of the spine and thorax. The chest is dropped and slumping occurs. The increased curving of the dorsal spine increases pressure within the discs.

In the near past roentgenologists frequently assumed that a disease of the epiphysis existed because this area was seen as a hazy and indistinct or irregular outline. These areas may be interpreted as irregularities in ossification interrupted by passage of nuclear substance through the end plate into spongiosa.

In the adolescent spine one finds about the periphery of the bony end plate, a cartilaginous ring. During the period of growth small areas of calcification or ossification appear within this ring and as time goes on these areas become confluent finally to present a bony ring. This ossifying or calcifying ring may be seen roentgenologically in its different stages of development. This picture will be referred to later in conjunction with roentgen diagnosis.

In brief summary of the development of these changes one may say that the destruction of the growth zone or epiphyseal cartilage zone may be caused by herniations of the intervertebral disc with resultant decrease in growth anteriorly in the vertebral body. While we have seen clinical kyphosis in the adolescent without radiological evidence of nuclear prolapse and again multiple nuclear herniations without kyphosis, we are sure that the nuclear herniations and cessation of growth of the body anteriorly are important considerations in the development of juvenile kyphosis.

CLINICAL PICTURE

Patients presenting themselves for examination do so usually for two reasons: poor posture or ache and pain in the back. A slumping posture has been noticed for a number of months and the child has complained of backache. On the other hand, the parent suddenly discovers the child has a badly rounded back and seems easily to become fatigued.

Ache or pain with fatigue are present in the majority of cases (Fig. 4). It is this symptom which brings attention to the back even in absence of curvature. The individual has a dull aching in the mid dorsal or low dorsal region, the severity of which may vary from a feeling of fatigue to aching and actual radiating pain on exertion. At times, the complaint of chest pains may be elicited with a "crowded" sensation in the thoracic cage. Many times the child is content to come straight home from school and rest at his own initiative rather than run and play after

Fig. 5 a, left Shows posture with increased curve dorsal spine. Head carried forward. b, Shows in forward bend the arcuate curve in mid and high dorsal spine.

school hours. This act of voluntary rest points to fatigue and is present at times without evident postural changes in the dorsal spine.

A greater percentage of children with back complaints are of the tall, ungainly type (Fig. 2). They have "sprung up overnight" so to speak in their growth. It has been our experience that these children complain of aching more than fatigue.

On examination one observes a rounded back accentuated by a slump of the shoulders. The head is carried forward, thus accentuating the contour of the dorsal spine. The chest is more or less flattened and plays a minor part in breathing. The abdomen is relaxed and abdominal breathing is pronounced. This picture is more in evidence in the tall individual (Figs. 5a and b). Increased lumbar lordosis in association with hyperextension of the knees and pronated feet completes the picture.

Palpating the dorsal spine one seldom elicits localized areas of pain or tenderness. Sharp tapping over the low dorsal spine with the heel of the hand may cause the patient to complain of pain especially in the forward bend position. The erector spinae group may exhibit spasm in the lumbar and dorsal spine equal bilaterally.

Fig. 6. a, left. Anteroposterior projection, shows paravertebral thickening. b, Lateral projection, shows increased dorsal curve, edging of bodies, variation of bony substance with reactive changes in bodies, and decreased intervertebral disc space.

The forward bend position accentuates the arcuate curve of the dorsal spine. Those individuals with tenderness bend slowly and with splinting action of the erector spinae group. This protective mechanism is clearly seen in the attempt to gain the erect position from the forward bend attitude. *The erect position is gained by first straightening the dorsal spine on the flexed lumbar spine. Following this maneuver the entire trunk is brought into extension.* This is a definite segmental movement as contrasted to the usual supple co-operative extension of all the segments of the normal spine and in our experience a diagnostic sign from a clinical standpoint.

The patient with a rigid back on attempt at side bending, and torsion does so with the hips, the lumbar spine acting in a minimal capacity. Hyperextension is a protected movement. *Less rigid backs will perform these maneuvers in an almost normal fashion except for the segmental movement on gaining the erect posture from forward bend.*

The spasm of the erector spinae is more evident in the dorsal and dorsolumbar regions. The musculature is tight and not infrequently tender to pressure. The lumbodorsal fascia may be contracted thus contributing to the lordosis. Hyperextension of the knees and relaxed or pronated feet are common. The pronated foot is observed at a 45 degree angle or greater. Seldom do the feet plant themselves parallel, in assuming a posture.

Unilateral tightening of the hamstring muscles has been credited for scoliosis. We have observed scoliosis in a small percentage of these children (Fig. 4) but have to date seen only one case of tightened hamstrings, bilateral. The kyphosis observed with a scoliosis have not shown roentgen evidence of abnormalities that may be said to be the cause of the lateral curve. One may find, of course, other changes of a congenital nature in the vertebral bodies that may accompany the kyphosis and produce the scoliosis. The logical explanation is the interruption of growth laterally as well as ventrally. The scoliosis may be either to right or left and is not severe. The rotation is way from the convexity.

The typical picture then is that of a generally rounded back with limited mobility, relaxed abdomen, increase in lordosis, and hyperextension at the knees. So far in our experience we have not seen the severe rounded kyphosis as depicted in foreign publications. Some of these approach the angular kyphosis. It is not logical to assume that the capacity of the spines of European children is less than our own children. However the demands made upon the backs of the European child may well be greater during this child's growing period. The economic status of this country and that of Europe differ greatly. More physical labor may be demanded of the child in Europe than in our own States.

ROENTGEN FINDINGS

The generally accepted criteria necessary to make a diagnosis of juvenile kyphosis are (Fig 6)

- (1) increased dorsal curve, (2) anterior wedging of the vertebral bodies in the dorsal region, (3) diminution of the intervertebral joint space, (4) serration of the anterior surfaces of the bodies, (5) nuclear herniations into vertebral bodies, (6) paravertebral thickening

The increased dorsal curve as seen in the lateral projection is a generally rounded arc, the anterior vertical height of the vertebral body less than the posterior vertical height. This wedging plus the narrowing of the intervertebral spaces produce the exaggerated curve. These findings occur in the low dorsal spine, usually from the seventh dorsal downward. Changes higher up are, however, seen.

Wedging of the bodies is due to arrested growth anteriorly. In the lateral projections the superior or inferior surfaces of the bodies may exhibit an arc-shaped or semicircular area of rarefaction immediately beneath which is found a circular zone of increased density due to irritative bone production. The escape of nuclear substance into the spongiosa releases tension within the intervertebral disc thus allowing collapse and the resultant picture of decreased intervertebral space.

Saw-toothed serrations of the anterior borders of the vertebral bodies are said to be the result of pressure phenomena exerted on a softened vertebral body. These serrations appear at the metaphyseal areas superiorly and inferiorly. One hesitates to accept the explanation of softened bone structure as we believe the vertebral body not primarily involved in the pathological process.

The irregular punched out areas seen on the superior and inferior anterior surfaces, so called "saw cuts," are not a part of the roentgen picture in arriving at a diagnosis. On the contrary they are calcifying or ossifying areas of the "corona" about the vertebral body in different stages. This is a picture of normal development.

Paravertebral thickening in the anteroposterior projection is described by Brailsford. This thickening runs along the lateral borders of the spine in the area affected. The significance is not definitely understood.

In the late stages one may see secondary arthritic changes. The close approximation of the vertebral bodies resulting from the collapsed disc may allow bridging. Lipping of margins may develop.

TREATMENT

Treatment naturally seeks to bring an end to symptoms and arrest or correct the existing de-

formity. Fundamentally, one attempts to establish a balance between the capacity of spine and functional demand. This balance is established during actively supervised treatment, namely by support, rest, and limitation of activity.

One may arbitrarily divide the treatment into three stages: (1) the period between the time the diagnosis is made to cessation of ache, pain, or fatigue, (2) from the cessation of symptoms to return to work and activity or, normal range and exertion, (3) from this point of activity to cessation of the growth period. It may be well to state that, in some cases, one may not get a patient to normal range of activity in the second stage, and it is only when the growth is complete that the individual reaches a normal sphere of activity. In other words, there is no second period here.

It is our belief that one cannot expect to change the general contour of a wedged vertebra when once developed. However, one can expect better posture and stronger spinal musculature under treatment. The clinical complaints of ache and fatigue are alleviated by adequate rest and support.

On arrival at a diagnosis the patient is placed at rest. By rest is meant flat in bed, being up only for a short time as demanded by meals and bathroom privileges. No other time periods are allowed the first 30 days. The bed should have a hard or firm mattress. The inner spring mattress is not tolerated. Boards placed longitudinally beneath the mattress and on the springs suffice. If there is a fair degree or well developed kyphosis, the child is fitted to a plaster-of-Paris shell.

The shell is made with the patient on his abdomen. The body must be straight on the table and a pillow under the abdomen to obliterate the lumbar lordosis. Plaster bandage is laid across the back, carried to the midaxillary line laterally and extends from gluteal crease to base of the scapulae. After 5 or 6 layers, a re-enforcing strap iron is placed in the long axis over these layers, having been bent to the contour of the back. These are incorporated with 4 or 5 more layers. Canvas strap is also incorporated to cross the shoulders and circle the abdomen to facilitate holding the shell snugly to the body. It is well to remember that this shell must be molded carefully about the hips and held snugly here while setting. After the setting the upper portions beneath the axillae are shaved down so that there is free movement of arms and no pressure dorsally to crowd the shoulder girdles ventrally. The shell after this process is then filled in with plaster cream in the dorsal portion which exhibits the

Back lying. a and b. Knees slightly flexed, abdominal retraction and flattening of lumbar spine for the count of three.

Back lying. a, Legs extended and arms at side, lumbar spine flat. Extend arms forward over head in arc-like manner keeping the lumbar spine flat. b, Legs extended and arms at side, lumbar spine flat. Bring legs into flexion keeping lumbar spine flat, relaxing down to extension maintaining the lumbar spine flat. Legs extended and arms at side with lumbar spine flat. Raise leg, left knee in extension and foot at right angle to leg. Slowly descend to extension, left lumbar spine flat.

Note: These exercises must be done on a flat hard surface.

3. Prone lying. a, Arms at side extension of dorsal spine from prone position. Attendant's hand at high lumbar spine so that only dorsal spine is exerting extension (preventing lordosis). The head must be held in extension with

the chin in (not hyperextending the cervical spine).

4. Table lying—prone. Flexion at thigh, arms in extension, extending legs holding lumbar spine flat, alternate extension of legs.

5. Sitting back to all. With hands clasped back of head, circumduction of shoulder girdles.

6. Sitting back to all. With arms parallel to ground, overhead extension maintaining erect and extended lumbar spine.

7. Standing exercises. Arms clasped back of neck. With lumbar spine flat, forward bending. With legs, maintaining lumbar spine and dorsal spine in extension.

8. Sitting. Biceps head along stretching.

Note: These exercises are to be given beginning approximately at five times and going up, keeping beneath the level of fatigue and discomfort. Patient gradually working into the table flexion sitting, and standing exercises from initial back lying and prone lying exercises.

greater kyphotic point. It is well not to fill in completely to give a flat surface initially, gradual obliteration of the kyphotic impression can be accomplished over a period of 1 to 2 months without discomfort to the patient.

Some children will not tolerate this plaster mold over an hour a night in the early periods of treatment. Usually it is the patient with spasm. This condition is met by baking twice daily for 30 minutes followed by mild relaxing massage. When physiotherapy is available it is carried out in a regular schedule. Next best is teaching the parent the technique of massage and baking at home. We are convinced that the physiotherapeutic measures have much to do with the relief of symptoms, and in these cases exhibiting spasm, are just as important as rest.

The competent physiotherapist working daily with a patient will determine the gradual disappearance of spasm in the *erector spinae* group and in conjunction with the attendant, arbitrarily determines the gradual increase in activity. If after a month the back is free of ache and is more or less loosened up, the child is allowed periods of supervised activity. These may be 1 or 2 hours in the mid-morning and the same period in mid-afternoon. Between times the patient continues to remain at rest in the shell.

At this period are begun exercises in addition to the bakes and massage. Initially, they are back lying and prone maneuvers to be described. They are supervised by the physiotherapist who can gauge the time and vigor of the exercises, gradually adding to the routine.

As the child develops tolerance and strength, standing exercises are brought in, and, when the patient fully understands the routine, he is allowed more time and activity.

In those patients with a well developed kyphosis wherein the posture does not correct, a spinal brace¹ is applied. It is constructed high in front with pressure points just below the clavicles and low in back. These patients earlier in the treatment, after a month of rest, may be placed in a plaster-of-Paris body cast molded high in front and low in back. We have made it a practice of keeping this cast on a child from 3 to 6 months, changing plasters each 2 months as necessary. Not infrequently a semi-permanent celluloid jacket is used.

The ambulatory case, when an out-patient, continues his exercises and wears the shell nights. If in a brace, this same routine continues. In cases in which carriage and posture are now the only problem, the massages and bakes are discontinued.

On the patient is placed the responsibility of exercises and the wearing of the shell at night.

How long restricted activity continues and to what degree, depends upon posture and the clinical picture of the back. These factors are determined only by repeated clinical examination. In our experience repeated x-ray examination has been of no practical value over short periods of time (under 6 months). If after 6 to 18 months the posture remains satisfactory and there are no complaints, the plaster or spinal brace is removed half days. It is during this period that a discrepancy may arise between the capacity and function, the continued absence of symptoms, laxity on the part of the patient and parent may allow too much activity and symptoms return. The conscientious patient progresses without pain and the support is removed completely.

A year to 18 months in a brace is not excessive, and in children of 12 to 15 years 3 or 4 years is not unusual. As the patient grows and develops a greater muscular capacity, his activity increases and gradually he enters the sphere of normal exertion. Stage three continues up to cessation of the growth period, and the properly supervised individual will keep his carriage and posture through this period.

It is interesting to note that our foreign contemporaries have an advantage in handling children. The regimentation of the child in large clinics is an accepted fact and classes are held daily with obligatory attendance. The classes are uniformly carried out with specified exercises and over long periods of time. We are of the opinion that if these adolescents are not protected from themselves until they fully appreciate their condition or until the full growth is attained, they are sowing seeds of chronic indefinite low grade backache of later years.

CONCLUSIONS

1 Juvenile kyphosis is a clinical entity of not uncommon occurrence. It is seen most frequently between the ages of 10 and 14 years, females predominating.

2 The true etiology is not definitely understood.

3 Roentgenograms reveal a characteristic picture.

4 Juvenile kyphosis is a self-limited disease. Treatment aims to alleviate symptoms and arrest the deformity through rest, physiotherapy, and temporary spinal support.

5 Juvenile kyphosis, if not properly treated may lead to chronic backache and to permanent deformity.

¹ Described in Chapter 3 Jordan's Orthopaedic Appliances (13)

THE RESULTS OF SPLENECTOMY IN GAUCHER'S DISEASE

VICTOR W. LOGAN, M.D., New York, New York

IN 1882 Gaucher described the splenomegaly which bears his name. He considered it a primary tumor of the spleen, but later investigators, notably Pick (22), Mandelbaum, and Epstein have shown that it is due to a disturbance of lipid metabolism, resulting in the deposit of kersin in the cells of the reticulo-endothelial system.

The clinical features of the disease are a progressive splenomegaly, a tendency to hemorrhage, brownish yellow discoloration of the skin, and wedge-shaped pingueculae. As the Gaucher cells develop in organs other than the spleen, they give rise to secondary clinical types. An osseous form of Gaucher's disease has been described by Pick (23). Destruction of bone with fracture or deformity occurs in about half of all cases. Neurological signs may predominate, especially in infants (1). Lesions of the lung (19) and kidney (14) have been described. The liver enlarges more slowly than the spleen, and a late cirrhosis may occur. Lymph nodes are occasionally enlarged.

The blood picture is not striking. There is a mild anemia with leucopenia. The differential count is normal. The thrombocytes are often reduced, but the bleeding and clotting time are normal. The fragility test is normal.

Diagnosis can be made from examination of the bone marrow by sternal puncture (33), which has displaced the dangers of splenic needling. Biopsy of an enlarged lymph node revealed the diagnosis in the cases reported by Hoffman and Makler and Donovan. The Gaucher cell is a large endothelial cell with grayish white cytoplasm containing fibrillae. The nucleus is small and eccentric. The cell contains the lipid kersin, a cerebroside.

The disease is familial, congenital, and possibly hereditary. Anderson has suggested that it is transmitted by unaffected males. (My own case lends some support to this idea.) Although it appears to have a predilection for the Jewish race, it occurs in members of all races, including negroes (13, 29) and orientals (31). Contrary to former belief, the sex incidence is about equally divided between males and females. Atkinson analyzed 103 cases (children) of whom 53 were females and 50 males.

Gaucher's disease usually becomes established early in life, but the progress of the illness is so chronic in some cases that it escapes notice until

long after maturity. Siegmund's case, quoted by Hoffman and Makler is the youngest patient on record, being 1 week old. Wechsler and Gustafson recently reported a case in a woman 71 years of age. Horsley and his associates found in a study of 71 cases, that over half of them were recognized before the age of 8 years.

Death usually results from intercurrent infection, often pneumonia. Melamed and Chester's patient, and Ullrich's also, died of the osseous form. Rowland and Aballi and Kato have called attention to an acute, fatal, infantile form with neurological symptoms.

Gaucher's disease is closely allied to the other disorders of lipid metabolism. These are Niemann-Pick disease and Hand-Schuller-Christian disease. Tay-Sachs disease (congenital familial amaurotic idiocy) is now considered to be a cerebral form of Niemann-Pick disease. These "xanthomatoses" have been amply discussed by Pick (22).

There is no specific treatment for the disease. Potter and McRae felt that liver extract helped one of their patients, but there has been little subsequent enthusiasm for this suggestion. X-ray radiation over the spleen had no retarding influence on the growth of the organ in either Pack's case or mine. In both cases it produced anemia, and therefore it seems to me to be a harmful treatment. Splenectomy, which was first performed for Gaucher's disease in 1895 (24), remains the most hopeful palliative measure. The principal objection to the operation is its high mortality. There is a conviction, possibly based on the first 10 recorded splenectomies for Gaucher's disease (11) that the operative risk is 20 per cent, since 2 of the 10 patients succumbed. Atkinson states that 7 of the 47 children, who had had splenectomy for Gaucher's disease, died after operation. This suggests a mortality rate of about 15 per cent in children. Whipple reported but 10 deaths in 106 splenectomies performed for various reasons in his Spleen Clinic at the Presbyterian Hospital. Since the Gaucher spleen, while enormously large, is one of the easiest spleens to remove, owing to the fact that it is rarely adherent, the current mortality rate must be much less than 20 per cent.

The immediate effect of splenectomy in exsanguinated children is often miraculous. Both

Myers (19) and Ulrich's infants were essentially moribund prior to operation. Several authors, including Moeller have felt that splenectomy hastened the rate of bone involvement. However de Lange who had followed two sisters for 9 years, observed that the skeletal changes were less marked in the splenectomized girl, although both children had lesions of the hip and tibia.

Indications for splenectomy are hemorrhage (especially when the platelet count falls below 100,000) and the discomfort of a large abdominal tumor. In Pool's case (26) the compelling reason was a desire to bear children, as the first pregnancy had terminated in a miscarriage. Hunter and Evans reported that their patient had 3 miscarriages, attributed to the enlarging spleen.

Late reports on splenectomized cases are unfortunately rare. For this reason I am reporting a new case 7 years after operation, and shall present notes on the present status of several well known cases previously described in American literature.

REPORT OF CASES

A. S., young unmarried woman, 28 years of age, was referred to us in January, 1932, by Dr. Bernard Samuels because of small laceration of the lower eyelid had bled for 4 days. Two years previously, she had bled overmuch after the extraction of tooth. Nose bleeds are rare but bruising is common. She had lost 7 pounds from dieting to reduce the size of her abdomen. No pain or dragging had been felt. She is employed in useful capacity in the office of hospital planning expert.

The family history is interesting. Her father is half Jewish, but there is no other Jewish ancestry. One of her brothers had large spleen. He was years younger than his sister and had known for 6 years (from the age of 12) that his spleen was enlarged. As he lived in malarial region of Louisiana, no attention had been paid to it yet he had never had chills and fever. During the 3 years he was under observation in New York the spleen did not increase in size. His blood count in May, 1918, as normal.

Physical examination of the patient showed tall, pale young woman, with small healing laceration of the lower right eyelid, oozing blood. The heart and lungs were normal. Traube's space was flat on percussion. The abdomen was full, especially on the left. A hard, smooth mass filled the entire left half of the abdomen, with notch at the umbilical level. The mass extended deeply into the left iliac fossa. The liver edge was not felt. There are several large bruised areas on the skin, and one over the thigh. Superficial lymph nodes were not enlarged. There was no pigmentation. Punguercles are absent.

The patient is quite anemic and had leucopenia, as shown in the accompanying blood tabulation. The thrombocytes count as 50,000. The blood loss is quickly made up after control of the bleeding by suture. The spleen continued to grow but there are no symptoms except fatigue. The diagnosis seemed reasonably clear for Gaucher's disease, but it was suggested that x-ray therapy be tried. This merely resulted in restoring anemia, without controlling the continued growth of the spleen. By the end of March the organ is occupying much of the right iliac fossa, having crossed the midline like a boot. Opera-

tion, as recommended because of the great size of the spleen.

The patient elected to go to her home in Surrrept, here on June 5, 1932, Dr. E. L. Sanderson of that city took out the spleen and sent me his operative report. "We removed the spleen, which weighed 9 pounds after removal. Of course it is much larger until tied the artery and applied gentle pressure before tying the vein. There are no adhesions and the operation is comparatively easy. She has had an uneventful recovery. Our pathologist makes positive diagnosis of Gaucher's disease. This was also the opinion of Dr. Ralph G. Stillman of New York Hospital, to whom I submitted sections of the spleen, sent by Dr. Sanderson.

Following her convalescence, the young woman came back to New York, here she resumed her work. Last year (1931) she returned to her home to look after her mother who was ill. There has been no clinical evidence of bone involvement, although no recent films have been made. Studies in 1932, about a year after operation, showed minimal thinning of the cortex of the femur shafts. The blood count shows slight reduction in the red cells and persistent leucopenia, with normal differential count. On one occasion, uncolored red cell as seen per os, late blood cells. Pigmentation and pinguercles have not developed. The patient says that she feels fine.

Pool's case. I. 9. Pool (3) reported the case of young married Jewish woman, 5 years of age, who had in the past year begun to lose weight and strength. She had been explored by another surgeon, who presumed that the cause of miscarriage was an ovarian cyst. Although the mass was identified as spleen, it was not removed. Five months later she came under Dr. Pool's observation. He found an enormous spleen, extending to the anterior superior spine on the right and almost into the pelvis.

Splenectomy was done on January 5, 1909, because the patient desired to have children. Pre-operative studies of the blood showed mild secondary anemia, without leucopenia, while the platelet count was normal. Pathological studies of the spleen showed typical Gaucher's disease. The case is fully documented in the monograph *Surgery of the Spleen* by Pool and Stillman (28).

In 1913, 7 years later Pool (26) again reported the case. "Her health has been good with one exception. Four years ago her left hip became painful. It was put in plaster in another hospital for 6 weeks and the joint is now motionless and painless. She has decided to have examination of the skull and other bones show no evidence of disease except in the left hip joint, where there is definite destructive process involving the head of the femur. The head is mottled, there is definite bone absorption and irregular calcification. The greater trochanter shows decalcifying process and the medullary substance in the shaft shows nothing for about two-thirds of the shaft. These changes are interpreted as the result of Gaucher's disease.

In 1920 Pool and Hipsley (27) reported that the bone changes in the hip had not progressed and that no new lesions had occurred. At this time the patient had 4 living children and was expecting third.

Dr. Pool has kindly allowed me to make use of his recent notes on this case. He is now 44 years old. Nineteen years have elapsed since the splenectomy. In the past year she has had some pain in her left shoulder. X-ray of this region shows no bone destruction, although one observer thought there is some cortical thinning. The hip has shown no further change. A sternal bone marrow puncture revealed no Gaucher cells, but seems remarkable. The blood picture is given in the accompanying table. There is no pigmentation of the skin and the liver is not enlarged. Pinguercles have not appeared. The patient looks well.

Dr Paul Kennell off he did the hist count, made the following comment: Anisocytosis plus, polichocytosis plus toxic granulation plus. Bleeding time 35 minutes-tournaquet test slightly positive. Clotting test moderately positive. clotting time 38 minutes (normal 0-1 minutes) clot retraction fairly good, clot fragility quite fragile hemostatic 38.5 per cent, album index 0/95 prothrombin 55 per cent normal fibrinogen (normal) reticulocytes 3 per cent, platelets 600,000 nucleated red blood count in smear.

Erdmann and Moorhead case. In 94 Erdmann and Moorhead reported the case of girl, 3 1/2 years old, upon whom they had performed splenectomy for Gaucher's disease on June 6, 9. This as the tenth splenectomy for Gaucher's disease reported in the old literature. This child as the fourth in the family. Her eldest brother had developed, in the second year of his life, large liver and spleen, with anemia and leucopenia. At the age of 6 he died of fulminating pneumonia. Although an autopsy as done, he presumably had Gaucher's disease.

At the time of the girl's operation, the liver extended inches below the ribs, and the spleen reached below the umbilicus and beyond the median line. Splenectomy as performed because of progress, loss of strength. Diagnosis as confirmed by studies of the spleen. The authors' final notes are made on October 6, 9, 16 months after the operation, when the child was reported still and strong.

She is now 3 years of age. The only dramatic episodes since the operation has been an appendectomy in 959, without complications, and severe fall from home in 956. This resulted in compression fracture of the body of the second lumbar vertebra, without serious sequelae. Films of the spine at this time failed to show evidence of Gaucher cell infiltration.

In 93 the liver extended to the umbilical level in the mid-clavicle line. The skin on the anterior chest wall was prominent. Mitral and aortic systolic murmurs are noted. 939 there as transient numbness of the right hand.

While this patient cannot be considered to be in perfect health, she has not suffered from gross bone destruction nor has she developed a severe or persistent nemia. The enormous liver may portend an eventual cirrhosis syndrome. I have been unable to find any other case in the literature which has been followed as long as this one 18 years, since splenectomy. It abundantly refutes Mueller's conclusions that the outcome of all patients operated upon at a young age is death either shortly after the operation or a few years later (18).

Pack and Silverstone's case. In 938 Pack and Silverstone reported case of Gaucher's disease occurring in a 5 year old single Jewish woman, who came to the clinic of the

Memorial Hospital in 932. She gave history of progress as enlargement of the spleen and severe epistaxis for 3 years, and as found to have large spleen and liver, mild anemia, with leucopenia, and symptomatic infiltration of the upper lobe of the left lung. After an absence of 3 years, she returned in January 935, having developed pigmentation of the legs, slight prostatic cough, and further enlargement of the spleen and liver. She had one small hemoptysis. The blood picture revealed marked anemia, with platelet count of but 67,000. Because of the purpuric manifestations, which are obviously due to the thrombocytopenia, splenectomy as performed on May 4, 935. The spleen weighed 3500 grams.

Improvement following the operation as striking. She gained pounds in 4 months, the liver returned to normal size, and the blood platelets rose to 320,000 with corresponding increase in all the blood cells. In spite of the clinical improvement, films of the chest showed increased infiltration. Pack's comment on the lung lesion as "the infiltration process in the left upper lobe of our case as interpreted as probable tuberculous, but in the absence of confirmatory evidence for tuberculous Gaucher cell infiltration may reasonably be considered."

Eleven months after splenectomy pain occurred in the right knee. Films at this time revealed osteoporotic changes in both femora and tibiae, with no changes in other bones. Her general health as good.

Dr Pack has kindly furnished me with recent notes on this patient. Late in 938 tubercle bacilli were identified in the sputum and since then the patient has been treated by her family physician. He report continued small hemoptyses in spite of repeated artificial pneumothorax treatments. Gaucher cells have not been reported in the sputum.

There has been increasing involvement of the skeletal system, especially in the upper portion of the right femur.

Which shows pathological fracture in December 939. At the present time, April 8, 940, the patient is still on crutches. Films in January 939, showed osteoclastic areas in the shaft of the left humerus and destruction of the right ilium, sacrum, and pelvis. The patient is fairly anemic.

The rapid rate of involvement of the skeletal system in this patient suggests poor prognosis. However it is interesting that the right tibia, the first bone involved has shown remarkable healing power. This phenomenon has been seen in Pool's case and was also commented on by de Lange.

In spite of the finding of tubercle bacilli in the sputum since the publication of this case, one wonders whether the original infiltration, so long silent, was not due to Gaucher cell infiltration with secondary tubercular infection. Myera de

BLOOD COUNTS, PACK AND SILVERSTONE'S CASE

-935	60	6,291,000	12,700	30	43			
10-29-39	70	5,574,000	10,200	46	35			
10-19-40	60	5,700,000	8,000	60	20	8		

scription of the lungs in his patient showed many points of resemblance to the lung lesion of this case, but without the finding of tuberculosis at autopsy Hoffman and Makler state that 8 of the 89 cases reviewed by them (including Gaucher's case) succumbed to tuberculosis. Perhaps more critical study of the lungs of these patients would have revealed Gaucher cell infiltration.

Cushing and Stout's case In 1929 Cushing and Stout reported 2 cases of Gaucher's disease. Dr Stout tells me that he has no further information about the first case.

The second case was that of an American woman of 33 years of age, who had suffered from childhood from severe epistaxes. At the age of 29, $3\frac{1}{2}$ years before splenectomy, she had developed stiffening, pain, and shortening of the right hip. She had all the stigmas of Gaucher's disease. On August 26, 1924, Dr Whipple removed her spleen which weighed 1017.5 grams. In 2 months she had gained 17 $\frac{1}{2}$ pounds, pigmentation lessened, and the liver was no longer palpable. In December, 1924, the head and neck of the femur were resected and sequestrums removed. Gaucher cells were found in great numbers in these fragments. The authors' last report stated that in April of the following year the lower part of the right femur had become involved.

This patient is now 49 years old, and 15 years have elapsed since her splenectomy. She is being followed in Dr Whipple's Spleen Clinic at the Presbyterian Hospital. Data regarding this patient will doubtless appear in future publications from that source. She is moderately anemic (see Table II).

OTHER LATE REPORTS ON SPLENECTOMIZED CASES

De Lange, already referred to, followed two sisters for 9 years, one of whom had been operated on. She found that the liver increased in size at first after splenectomy, but in later years ceased to enlarge. Pigmentation appeared in both girls at the same ages, but later disappeared in the splenectomized girl. This observation has been made by others. Both children had destructive lesions of the left hip joint.

Mueller gave the final report of Ullrich's case. This child of 3, in 1930, was almost *in extremis* from uncontrollable nasal hemorrhage, and made a remarkable postoperative recovery, only to succumb to an osseous form of the disease, with terminal meningeal symptoms at the age of 9. The finding of an accessory spleen the size of an apple, at autopsy, was one of the features of this case.

Myers (19) in 1937 reported the autopsy findings on a child 8 years old, who had had a splenectomy in September, 1931 (20). Just prior to operation the erythrocyte count was below 1,000,000, because of three severe nose bleeds. Contrary to expectations, the operation proved life saving. The lower end of the right femur was incised for a supposed osteomyelitis in April, 1932, Gaucher cells being found in the exudate. The dorsal ver-

TABLE I—RESULTS OF SPLENECTOMY 5 OR MORE YEARS AFTER OPERATION

Author	Years after operation	Remarks
Erdmann and Moorhead	31	No bone lesions. Liver large.
Pool	19	Left hip involved 3 years after operation. Now quiescent.
Cushing and Stout	15	Right hip involved $3\frac{1}{2}$ years before operation. Now under supervision at spleen clinic, Presbyterian Hospital.
Hunter and Evans	13	No bone involvement. Occasional hemoptysis. Liver enlarged.
de Castro Freire	11	No complications.
de Lange	8	Liver enlarged. Left hip joint, left tibia involved after operation with subsequent healing.
Logan	7	No complications.
Melamed and Chester	7	Died from extensive osseous type. Involvement of bone antedated operation by 7 years.
Muller (Ullrich's case)	6	Extensive osseous invasion soon after operation. Died.
Myers	5 $\frac{1}{2}$	Both femurs involved soon after operation. Died of pulmonary. Gaucher cell invasion and progressive osseous destruction.
Pack and Silverstone	5	Right knee involved soon after operation with later fracture of right femur and involvement of left shoulder. Pulmonary tuberculosis.

tebral bodies and the lower end of the left femur became involved during the next 2 years. In August, 1935, the lung became infiltrated and death came January, 1937, from a terminal bronchopneumonia. Gaucher cells were found in the enlarged mediastinal and hilum glands, while the air spaces of the lung were compressed by Gaucher cells developing in the small subserous and interlobular lymph nodes. There was no evidence of tuberculosis.

De Castro Freire in 1935 made a second report of the case which he had published in 1926. This concerned a girl of 8 years of age, the first case of Gaucher's disease to be reported from Portugal. Eleven years after her splenectomy, she was planning to marry at the age of 19. The liver had not enlarged and the hemorrhagic diathesis, which had been responsible for the decision to remove the spleen, had not recurred. There had been no apparent bone involvement.

Hunter and Evans have reported one of the oldest cases on record. This woman of 60 years of age became pigmented at the age of 8 and had nose bleeds from the age of 10 onward. When she was 29 the spleen was found to be enlarged. She

TABLE II.—LATE BLOOD COUNTS OF PATIENTS WITH GAUCHER'S DISEASE AFTER SPLENECTOMY

Author	Hb per cent	RBC	WBC	Poly per cent	%c RBC	Platelets	Time after operation
Frisman and Moorhead	8	4,000,000	12,500	70			27
Pool	90	4,000,000	15,000	53	1 ^a	300,000	1
Carling and Starr ^b	70	3,800,000	8,000	34	4/1000	215,000	5
Hunter and Evans	67	3,000,000	3,150	65	1/1000	80,000	
de Castro Freyre	65	3,100,000	3,000	49		60,000 (Spheria)	21

had 2 living children and had had 3 miscarriages. Before her spleen was removed she had begun to have hemoptyses. After the operation, performed in her forty-seventh year the abdominal pain, which was the reason for the splenectomy disappeared. Pigmentation decreased. At the time of Hunter and Evans report, 13 years after the operation, she tired easily, suffered from head aches, had developed pinguiculae and again suffered from occasional hemoptyses. Signs in the lung were negative. The liver edge was 2 inches below the costal border.

Melamed and Chester in 1938 gave the final report of a 26 year old male, who had suffered from an osseous type of Gaucher's disease from the age of 13 years. When he was 20 years old the spleen was removed. He had purpuric manifestations without thrombocytopenia before the operation and was largely relieved of these for some years. In the last years of his life the bone destruction was so marked that he was bedridden. Invasion of the bone marrow finally produced a malignant anemia, which was heralded by the appearance of increasing numbers of nucleated red cells (Table II).

ANALYSIS OF STUDY

In reviewing these cases, one is struck by the uniform improvement in the clinical picture immediately following splenectomy. Hemorrhage is controlled, the patient gains weight, the liver decreases in size, and pigmentation often lessens or disappears. The hemorrhagic diathesis is not always cured by splenectomy. Carling and his associates found that their patient continued to

have hemoglobinuria after splenectomy. Hunter and Evans reported recurrence of hemoptyses after splenectomy as noted, and Pack's patient has had similar experiences. Ulrich's patient is reported by Mueller to have had recurrent ecchymoses 2 years after operation. In most cases, however hemorrhage does not recur and the thrombocytes maintain a normal level. The chief change in the blood picture after splenectomy is the replacement of a leucopenia with permanent leucocytosis. This is true of most of the cases reviewed in this paper. The differential count is essentially normal both before and after splenectomy. Nucleated red cells appear from time to time, but their numbers are not great until the bone marrow is almost completely replaced by Gaucher's cells in the malignant osseous type (see Melamed and Chester's case). The degree of leucocytosis appears to have no relation to the amount of bone destruction. It is probably a nonspecific reaction to splenectomy. Connors reported leucocyte count of 13,000 in one of his patients 17 years after a splenectomy done for traumatic rupture of the spleen.

It has been alleged that splenectomy precipitates or hastens involvement of the bones in Gaucher's disease. This will be difficult to prove until someone has the opportunity to remove the spleen in one of a pair of identical Gaucher's twins. De Lange felt that there was retardation of the skeletal involvement in the splenectomized girl as compared to the sister. Of the patients reviewed in this paper 4 had bone changes before splenectomy, 4 developed bone lesions after splenectomy while 4 others had no evidence of skeletal

involvement in the 7, 11, 13, and 28 year periods following their respective splenectomies. As splenectomy is only done at a time when Gaucher cell infiltration is in a rampant phase, it seems unreasonable to attribute postoperative bone involvement to the mere removal of the spleen.

As a general rule, the earlier in life that the disease gives rise to symptoms, the worse the prognosis, and therefore the earlier the splenectomy, the worse the outlook. Yet Erdmann and Moorhead's case and de Castro Freire's show that one may not be arbitrary in withholding the benefits of splenectomy from young children. In neither of these patients has purpura recurred, nor have bone complications arisen.

As to the ultimate value of splenectomy in Gaucher's disease, the long histories of these patients is encouraging. The bone lesions in the older patients have not progressed to total skeletal involvement except in the fatal case described by Melamed and Chester, while in certain instances there has been evidence of arrest and repair. They are in fair general health and carry on as normal individuals. One of them has raised a family. Their present ages are 33, 36, 44, 48, and 1 was aged 60 in 1929 (Hunter and Evans' case).

Of the 5 children, 2 died before the age of 10 years. The others have arrived at the ages of 12, 19, and 31 years. Of the splenectomized patients who have died, 2 died of the malignant osseous form and 1 of the pulmonary form. None died as a result of intercurrent infection. Although this series of cases, followed for more than 5 years, is small, it is of interest to note that there has been freedom from acute intercurrent infection in the entire group. If splenectomy increases the resistance of the Gaucher patient to acute infections, which is reputed to be the chief cause of death in this group of individuals, the operation would be justified on this ground alone.

SUMMARY

1 A short review of Gaucher's disease is given, with the report of a case 7 years after splenectomy.

2 Late reports are made of several cases previously described in the literature, ranging from 5 to 28 years after splenectomy.

3 Similar cases from the world literature are reviewed.

4 The mortality rate for splenectomy in Gaucher's disease is nearer 15 than 20 per cent. Those patients who survive the operation show striking immediate clinical improvement, which is usually maintained, except in very young children.

5 The theory that splenectomy hastens the involvement of bone in Gaucher's disease is questioned.

6 It is suggested that splenectomy increases the resistance of the Gaucher patient to infection.

I wish to express my thanks to Dr. Eugene H. Pool, Dr. John J. Moorhead, Dr. George T. Pack, Dr. Arthur Purdy Stout, and Dr. Allen O. Whipple for their generosity in allowing me to use data on their cases from their private files.

WAR MEDICAL SERVICE IN GREAT BRITAIN

THE success of the British fighting forces in opposing the Nazi Colossus has appealed to the imagination and sympathies of the American people to such an extent as to obscure the working of some of the machinery that made such achievements possible. The result alone seemed important and only a few bothered to lift the hood to look at the engine. Among the various essential parts of this mechanism is the medical organization, and it may be of interest to American doctors to learn something of how it is working and what it is accomplishing.

In the first place it is essential to point out that the medical corps of the army and navy are playing but a small part in medical relief work in Great Britain. In defensive preparations prior to the war the planning commissions envisaged the probability of large scale air raids on cities and industrial areas from the outbreak of the war and it was fore-

seen that the care of civilian casualties might be a more important problem for the medical organization than that of military casualties. In addition the civilian population would present other health problems growing out of the evacuation of refugees from the cities and the crowding together in public shelters of those who remained. So in addition to the medical corps of the army and navy and of the separate air force a fourth civilian organization known as the Emergency Medical Service or "E M S" for short was set up under the Minister of Health.

The responsibilities of these four different services are separate but related. The medical corps of the Royal Navy is the most nearly independent service and comes closest to doing what it was intended to do, namely care for the illnesses and casualties among the naval and fleet air arm personnel. It has its hospitals scattered about England and elsewhere, chiefly at the various naval bases. The writer visited one of these hospitals in October. It was situated in a coast city that was very exposed to air bombardment. The buildings were ancient and built in years when sail still provided the motive power of ships. The receiving and operating rooms were well organized in the subterranean vaults and were well organized. Each case was inspected on admission and tagged either to be sent to the resuscitation room, to the operating room via x-ray, or to the ward. Shock teams were organized to work in the resuscitation room and were able to draw on an ample blood bank and stores of plasma or dried serum obtained and prepared by the hospital. A number of severe burn cases were under treatment and apparently this is a not infrequent type of

naval casualty resulting either from fires or bursted steam pipes. It is to be noted that this hospital handled civilian casualties as well as those suffered by naval personnel. Because of its exposed position patients treated there had to be evacuated as soon as they were transportable and they were then sent on to an E. M. S. Hospital farther inland.

The Royal Army Medical Corps maintains only a few general hospitals in England but does have a number of small camp hospitals where medical and minor surgical conditions are handled. A number of general hospitals were established in northern France during the time that the British Expeditionary Force was holding its sector at the front. Here too was assembled the best part of the fine motorized equipment organized for the medical and surgical care of the army in the zone of combat. These included mobile operating units, x-ray vans, laboratory and other cars. All of these were lost in the battles of Belgium and Northern France. The plans of medical organization called for the evacuation of the wounded from the army general hospitals to E. M. S. hospitals in England. These plans were put to a hard test in the evacuation of the wounded from Dunkirk. Most of the wounded had to be rushed from the place where they fell directly on board ship without receiving other than first aid treatment. Often it was several days before they reached their destination in hospitals in England. The difficulty of properly handling the wounded in the confusion of the embarkation and debarkation, with the well and injured hopelessly mixed may be well imagined. Yet somehow the authorities proved equal to the occasion and the wounded were sorted, loaded on hospital trains, and distributed all over England, for the main part to E. M. S. hospitals. Although many of the wounds proved badly infected and gas infection was common it was the gen-

eral impression that the condition of the patients upon arrival was less bad than might have been anticipated. This was generally attributed to the widespread oral administration of sulfanilamide begun at the first aid post and continued throughout the journey. Although there was no opportunity for proper control of the drug by blood level determinations and the dosage had to be regulated according to the judgment of the different doctors who were in charge, still the effect in general was beneficial and undoubtedly played a part in preventing many of the more virulent types of infections.

The Royal Air Force being an independent service, maintains its own separate hospitals for the treatment of its officers and men. Because of the importance from the standpoint of national defense of restoring flying personnel to service as rapidly as possible, special facilities were arranged for the prompt transfer of these men from other hospitals where they might be taken immediately after injury to the special R. A. F. hospitals where a staff of specialists was assembled and all facilities provided to bring about as quick a recovery as possible. Not all patients were transferred however and exception was made when the patients required special treatment which could be best obtained at other hospitals. This was the case with the burned aviators who were treated at special faciomaxillary centers maintained by the Emergency Medical Service under the direction of the distinguished plastic surgeon, Sir Harold Gillies.

Severe burns of the face and hands proved a common type of injury among aviators whose planes were set on fire in aerial combat. During the process of getting out of the cockpit in order to bail out by parachute their faces and hands were exposed to the flames while their bodies were relatively protected by their heavy flying costumes. These men were ter-

ribly disfigured and frequently required complete reconstruction of nose, mouth, and eyelids in addition to skin grafts to the face. Such operations must be done in different stages over a period of many months, but beautiful work is being done and they are being made fit again to return to human society. The burns of the hands also represented a difficult problem requiring co-operative effort from both plastic and orthopedic surgeons to achieve the best results. The study of these cases, the majority of which were treated in the beginning by tanning of the necrotic tissue with various solutions, led to the important conclusion that without prejudice to the use of tanning in other parts of the body, in the case of the face and hands it caused excessive tissue loss and scar formation and should be abandoned. An order to this effect was issued to the R A M C and E M S hospitals.

The Emergency Medical Service in the Ministry of Health is the new organization developed to meet the special conditions that were expected to arise in this war. It is entirely civilian and there is no uniform. It admits to its hospitals for treatment first, any disease or injury arising in or incurred by personnel of the military forces whether army, navy, or air force, second, civilians with injuries incurred as a result of enemy action or in the course of civil defense, and third, civil cases of any character that have to be sent in on account of the necessities of war, as for example the evacuation of a hospital that has been subjected to aerial bombardment.

At the outbreak of the war the E M S constructed or improvised a large number of hospitals throughout England. For the most part these were mental hospitals which were evacuated of their patients and converted to general medical and surgical use, or hut hospitals built usually about a nucleus of pre-existing buildings which supplied power and

service. The administration is regional under hospital officers and group officers. These men are responsible for supplying staff and personnel and also for the transportation and distribution of the convoys of sick and wounded who must be evacuated from regions threatened with aerial bombardment.

The city of London is divided into six or seven sectors shaped like a section of pie each with its apex extending into the central part and including one of the important teaching hospitals such as Guy's, St Bartholomew's, St Mary's, St Thomas', etc., which is supposed to control the whole sector. The sector stretches peripherally for a considerable distance, and its base may be as much as 50 miles distant from its peak. A number of E M S hospitals are included in each sector and theoretically these hospitals are staffed by doctors and nurses from the dominating hospital and medical school at the apex. This is in order that these hospitals may work together with the minimum of friction and that all of them may be utilized in the education of medical students and nurses. The medical staffs of the E M S are all in the employment of the Ministry of Health and for the most part on a full time basis, although some are on half time. The salaries are meager, ranging from 500 pounds for a junior physician or surgeon to 800 pounds for a senior with an additional allowance of 100 pounds for living expenses. It may be remarked in passing that private practice is so completely disrupted in London and many of the other large cities that many of the doctors are completely dependent on these salaries for their living.

Because of the constant threat of air bombardment a large number of the beds in the central hospitals must be kept empty. This is both for the protection of patients and also to provide facilities for the reception of the large numbers of air raid casualties that might

be produced at any moment by an unlucky hit. Most of the important hospitals in London have sustained severe damage from bomb hits and it is estimated that it will be necessary to replace the entire hospital plant of London at the end of the war. Emergency operating and nursing facilities have been organized in the basements of these hospitals and here are treated the ordinary urgent civilian conditions as well as the air raid casualties. Only small staffs of doctors and nurses are maintained. As quickly as possible the patients are evacuated and transported to the more outlying hospitals in the respective sectors where their security will be greater than in central London and better care can be given.

All of these hospitals are regularly supplied with citrated blood, plasma, and dried serum from one of the four blood depots organized by a committee of the Medical Research Council. In the American section of the Park Prewett Hospital at Basingstoke the blood depot supply truck called regularly every Monday and delivered twelve half liters of blood and took away the unused remainder of the blood that had been left from the previous week, to be converted into plasma. The blood supply service also replenished the stock of plasma and dried serum and kept it up to an

agreed level. This was a fine service and was available to all those hospitals which requested it.

Finally in any comment upon the medical organization in England one must pay tribute to the fine spirit of devotion and sacrifice of the doctors and nurses. These men and women have faced the dangers and miseries of air raids without complaint. Many have been killed or wounded. They have never stinted their services in furnishing medical and nursing care and in times of danger have remained with their patients and tried to provide for their protection. Their spirit has been typical of the English people as a whole and they have faced every trial with a jest. Frequently when I encountered a British medical colleague he would remark quite casually and as if it were a great joke that he had received news that his house in London had been hit by a bomb. Although this generally represented the loss of all that had been collected during a life time none of them wanted sympathy. But if one explored the matter further one might elicit some poignant remark such as "Well it is rather hard on my wife because she is too old to start all over again." One returns to the United States with the feeling that we Americans may take pride in our British heritage.

PHILIP D. WILSON

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IN the first chapter of *Gynecological and Obstetrical Pathology*¹ the author gives a brief review of the endocrinology of the menstrual cycle and pregnancy, and calls attention to the histological changes produced by the hormones involved

Each subsequent chapter starts with a short description of the normal histology of the particular part to be considered which is in turn followed by a description of the pathological changes. Brevity and conciseness characterize the descriptions throughout the book, however, each phase of pathology is allotted its proper consideration

The book contains 495 pages and 42 well chosen illustrations. All the illustrations, but one, are in black and white. A bibliography is presented at the end of each chapter. This treatise is a very valuable reference for the student or practitioner of gynecology

CHESTER C DOHERTY

FOUNDATIONS for further research in neurohistology have been laid in the 164 page monograph of Professor Boeke². The book is divided into four chapters which cover (1) innervation of skin, (2) the sympathetic ground plexus, (3) the relation of sympathetic interstitial cells to neurons and to humoral phenomena, and (4) a critical discussion of the neuron doctrine. The general objective of the work is the correlation of physiologic and histologic observations. In his study of regeneration of nerves to the skin, the author was not able to confirm Head's theory that protopathic sensibility was mediated by nerves of the sympathetic system, but found that such sensibility was a phase associated with regeneration of somatic nerves. Numerous examples are cited to show the widespread distribution of the sympathetic ground-plexus to all parts of the body. Interstitial cells are discussed with reference to their possible functions and the meaning of their presence in higher vertebrates to phylogenetic development as traced from invertebrates through *Amphioxus* and the sharks. The final chapter is devoted to pointing out some of the inadequacies of the neuron doctrine as it exists in its classical form, and a plea is made to regard synapses as living membranes which possess physiologic continuity. The syncytial character of many nerve plexuses is regarded to be out of harmony with the idea of strict discontinuity of individual neurites. The author states frankly that the treatise is colored by his own

opinions, but that much of the material deals with controversial subjects in which it is often better to leave a question open than to draw unwarranted conclusions

The book is better suited to the needs of the more advanced student in neurohistology or neurophysiology than it is to those of the beginner, because the author presupposes a knowledge of the literature on the part of the reader. It also should be very readable to the clinical neurologist. There are 48 text figures and a bibliography of 88 references. Some figures are taken from older works (as far back as 1894), but most of them are relatively new. The bibliography is representative rather than exhaustive

HAROLD A DAVENPORT

THE approach to the diagnosis of "the acute abdomen" by Cope³ is essentially a clinical one. A composite picture that includes the phenomena of pain, tenderness, rigidity, nausea and vomiting, and the localizing phenomena, plus such systemic signs as fever, pulse increase, and leucocytosis, is present with certain variations in all types of the acute picture. Clinical experience and judgment, with a discernment for shadings, enable us to differentiate, for instance, acute appendicitis from acute salpingitis, cholecystitis, or other lesions. This approach and clear appraisal of clinical symptoms is excellently accomplished in this compact volume now in its eighth edition

The subject matter is contained under the following chapter headings: principles of diagnosis in acute abdominal diseases, methods of diagnosis, appendicitis, perforation of gastroduodenal ulcer, acute pancreatitis, acute abdominal obstruction, intussusception, carcinoma of the colon, strangulated hernia, ectopic gestation, cholecystitis. There are other additional chapters on the colics, abdominal injuries, abdominal disease with genito-urinary symptoms, acute peritonitis, and diseases which simulate an acute abdomen

The author has wisely made the chapter discussing appendicitis the most extensive, as well as a pivotal point for differential diagnosis. The chapter is undoubtedly the best of the group. There is little room for fundamental difference of opinion with ideas expressed by the author. The clinical picture of each disease is well drawn and excellently written. One minor criticism might be ventured, namely, the presentation of perforated ulcer in clinical "stages"

¹GYNCOLOGICAL AND OBSTETRICAL PATHOLOGY WITH CLINICAL AND ENDOCRINE RELATIONS. By Emil Novak, A.B., M.D., D.Sc. (Hon. Dublin). F.A.C.S. Philadelphia and London: W.B. Saunders Co. 1940

³OXFORD MEDICAL PUBLICATIONS. THE EARLY DIAGNOSIS OF THE ACUTE ABDOMEN. By Zachary Cope, B.A., M.D., M.S. (Lond.). F.R.C.S. (Eng.) 8th ed. London: Oxford University Press 1940

This work is a handy volume—it is accurate, complete and groups acute diseases of the abdomen in one volume.
J. R. BRECKENRIDGE.

THE volume *Surgery of the Alimentary Tract* by Devine¹ is a large one as might be surmised from its title. It is divided into four sections: (1) the diagnosis of surgical dyspepsia, (2) the surgery of surgical dyspepsia and of the upper part of the abdomen, (3) abdominal emergencies which may involve either the upper or the lower part of the abdomen and (4) surgery of the lower part of the abdomen.

In the first section the author has made an unusual and instructive approach in thorough discussion of the dyspepsias, both gastroduodenal and retrogastric, or reflex. A thorough and sound exposition of the mechanism and correlated clinical picture is given. A wide section is devoted to liver—gastric, duodenal, and jejunal ulcer—duodenal diverticulum, gastritis and duodenitis, and carcinoma.

The second section of part one of the text deals with "precision" methods of diagnosis, chiefly x-ray and includes a chapter on the gastroscope.

Under "surgical procedures" there is an extensive and well illustrated section dealing with the operative surgery of the stomach, duodenum, bile tracts, pancreas, and spleen, as well as a section on post-operative complications. On the operative management of duodenal ulcer the author is less radically inclined than continental surgeons and perhaps less so than most American surgeons. If the "infective" type of ulcer he employs gastro-enterotomy in the "acidic" type partial gastri resection, his feeling being that in the ulcer of his peoples the "infective" type predominates. A considerable amount of space is devoted to the technique of resection for both ulcer and carcinoma and there are tremendous number of excellent illustrations—far more than are usually found in a text on gastroduodenal surgery.

In the fourth section are included appendicitis, carcinoma of the colon and rectum and diverticulitis.

One cannot but be impressed by the obvious experience of the author, as shown by the abundance of careful descriptive detail and illustrations in the preparation, approach, and performance of operations. The work represents a fine contribution to the surgical dyspepsias, and particularly it is an excellent reference volume for the surgeon interested in the surgery of the stomach and duodenum.

J. R. BRECKENRIDGE.

In the revised edition of Professor Grant's *A Method of Anatomy Descriptive and Deductive* an introductory section on the bodily systems has been added to the text material, and over 100 figures added to

the original set of illustrations—making a present total of 65. Many of the new figures are less diagrammatic and are therefore better representations of dissections than were those of the original edition.

The first section deals, in general terms, with the several bodily systems. Osseous structure is considered microscopically—bones are classified the significance of markings discussed—vascular foramina, elevations, facets, and foramina. Muscles are described on the basis of internal fascicular architecture and the physiological mechanism of contractions is described in simple terms. The vascular system is considered from many standpoints as is the volume of blood contained in the body as to the character of arteriovenous anastomoses as to special nature of alveoli, end-arteries, and cavernous tissue. Many helpful facts are recorded regarding vascular patterns in such special areas as nail bed and lip, cerebrum and spleen, erectile bodies. Topographically different parts are thus catalogued together on the basis of peculiarity in blood supply. By this means the student is introduced to a rationalizing scheme of study. The nervous, digestive, respiratory, urinary and reproductive systems are similarly treated in this preliminary section.

The regional account is followed by a section being devoted to each of the major subdivisions of the body, namely upper limb, lower limb, pelvis and perineum, thorax, head and neck. A closing section covers the autonomic nervous system, body types, the separate elements of the skeleton.

Throughout these sections the anatomical detail is presented with admirable ingenuity, simple mechanical principles, homely physical notions are abundantly cited in order to make structural facts familiar and, therefore, mentally manageable. Thus, in discussing the musculature the attachments of the upper limb the head is likened to guy ropes the looseness of the pectoral fascia is explained as adaptive to free thoracic movement during respiratory activity, marginal thickening of the scapula is said to prevent buckling of that bone when the serratus anterior pulls upon the inferior border the carpal bones are presented as modified blocks, altered from cubical to various other forms.

In the section about the abdomen the inguinal canal is likened to a channel whose roof consists of 3 arcades contributed by the triangular ligament, all it is pointed out, strikingly, that the abdominal viscera lie largely within the thorax cage (because of height of diaphragm) and within the pelvic bowl, the liver is described as resembling an oblong block with its intestines with its mesentery the kidneys with their retroperitoneal stratum are likened to 3 pages of book, comparatively movable after dissection.

In the section dealing with the anatomy of the lower limb complex anatomy is again simplified by comparison with common objects the space of the femoral triangle, with its combination as adductor canal is likened to funnel with a long spout the weight-bearing points of the foot suggest the supportive mechanism of tripod. The chapter con-

¹THE SURGERY OF THE ALIMENTARY TRACT. By Dr. EDWIN DEVINE, M.D. PHILADELPHIA: F. & J. C. BALLOU, The Williams & Williams Co.

¹⁰⁰ METHOD OF ANATOMY, DESCRIPTIVE AND DEDUCTIVE. By J. C. GRANT, M.D. CHICAGO: F. & J. C. BALLOU, The Williams & Williams Co.

tains tables of muscle action groups and time tables of epiphyseal development

The section on thoracic anatomy, in addition to dealing with the regular segregated items, discusses such varied general topics as posture, alteration in form of the bronchial tree, development of the heart and great arteries

The section on the anatomy of the head and neck is, like the preceding sections, replete with diagrammatic figures. Some of these are cryptic and would require an experienced student's knowledge for full understanding. Others are better representations of dissections or of gross sections, and are, therefore, distinctly helpful.

Professor Grant's *Method of Anatomy* resembles a manual more closely than it does any other type of treatise, but it differs from the standard manual in presenting concepts superabundantly. It is not a textbook of the regular systematic order, the bulk of its content being arranged upon a regional basis. The volume is not a substitute for an atlas, since the drawings are diagrammatic, it is not a dissector's guide, but is now accompanied by a small companion volume which serves the student in the latter capacity.

This book, which is essentially a manual of regional anatomy filled with concepts, is unique in its attempt to teach anatomy in such a way that underlying principles, rather than mere facts, are made its chief content. Certainly only a gifted teacher could formulate as many valuable notions as Professor Grant has included in his volume. His experience has allowed him to furnish some of the clearest bits of description yet encountered in anatomical writings. But in the commendable desire to clarify and to simplify, some important details of anatomy are omitted, simplification becomes so demanding that what remains of fundamental description is actually quite "traditional."

Professor Grant's provocative volume could scarcely replace any regular part of the student's anatomical library, but it could, with great profit, be added to such a library. For the graduate student its content would be inspiring, the surgical anatomist could profitably employ it as a source book for lecture material, and it would carry the young teacher glowingly through those beginning years which, customarily, are depressingly didactic. BARRY ANSON

THE author of *The Injured Back and Its Treatment*¹ does not claim that the content of this book is new. For those who have kept abreast of modern developments in trauma and diseases of the spine, it is intended as a compilation of modern concepts in this field and as a bibliography in which all important related work is made available. For those whose attitude toward back pain is one of fear and helplessness, a complete and concise course in the anatomy, pathology, physiology, diagnosis, and treatment of any related condition is available. For

the practitioner who for the first time sees the patient with a lesion of the spine or its related structures, the chapter on the routine examination of the back should prove most valuable, for it is the guide by which he may evaluate the patient's complaints, discard the irrelevant, and localize those factors playing a major rôle in the clinical picture. The editor has wisely refrained from accentuating those lesions which are amenable to operative management alone. The prolapsed intervertebral disc and other causes of cord and nerve compression are discussed but with the reserve warranted by their relative infrequency.

This book has been published at an opportune time. It is alone in the field and is a "must" number for the medical library. J K STICK.

NOT only have Lowsley and Kerwin² amplified and enlarged their original textbook on urology to a two volume work but they have succeeded in compiling one of the most comprehensive and valuable editions on this subject which has appeared in recent years. While the book is written primarily for the medical student, the general practitioner, and the general surgeon, it also provides a completely up to date reference work for the trained urologist.

General diagnostic procedures, with special emphasis on their practical value, are considered in great detail in the early text. Roentgenography of the genito-urinary tract is adequately considered and well illustrated. This is followed by an excellent chapter on anesthesia in urology. Embryology, anatomy, anomalies, and physiology of each division of the male genito urinary, and the female urinary, organs are fully described before injuries and diseases are discussed. The most outstanding feature of this work is the very complete consideration of treatment of all urologic diseases and anomalies. The excellence of the illustrations by Didusch clarifies each surgical procedure, making the work an atlas of urologic surgery in addition to the text. A full and complete bibliography is appended to each chapter.

This work can be most heartily recommended, not only as a textbook, but as a suitable reference which covers the entire field of modern urology.

VINCENT J O'CONNOR

IN the latest revision of their book about diseases of infancy and childhood, Drs Holt and McIntosh³ acknowledge the inability of any one or two authors to write with authority on such a broad specialty as pediatrics. Increasing specialization within the pediatric field has enabled investigators to acquire information and experience which it is impossible for the general pediatrician to obtain.

¹CLINICAL UROLOGY. By Oswald Swinney Lowsley, A.B. M.D. F.A.C.S. and Thomas Joseph Kerwin, M.A. M.S. M.D. F.A.C.S. Vols. 1 and 2. Baltimore, The Williams & Wilkins Co. 1940.

²HOLT'S DISEASES OF INFANCY AND CHILDHOOD. A TEXTBOOK FOR THE USE OF STUDENTS AND PRACTITIONERS. By the late L. Emmett Holt, M.D. and John Howland, M.D. Revised by L. Emmett Holt, Jr. M.D. and Rustin McIntosh, M.D. 11th ed. New York and London: D. Appleton Century Co. 1940.

¹THE INJURED BACK AND ITS TREATMENT. Edited by John D. Ellis, M.D. Springfield Ill. and Baltimore Md. Charles C. Thomas 1940.

On this account the writers have enlisted the aid of some thirty of their colleagues who have collaborated in certain features of the work. By this means the authors have been able to maintain uniformity of style and presentation, and at the same time to take advantage of the special studies of workers in some particular branch of pediatrics.

The result is a textbook which presents in admirable fashion the essentials of present day pediatric knowledge. Several sections of the book have been entirely rewritten, and others extensively revised and enlarged to bring the subject matter up to date.

This book can be heartily recommended both to students and practitioners. STANLEY GIBSON.

THE volume *Physiology of the Fetus* by Windle, comprising a modest 326 pages, is packed with well indexed and tabulated information bearing strictly on the title. It covers in considerable detail such matters as the function of the fetal circulation, blood, respiration, digestion, elimination, endocrines, the neuromuscular system, and sensation.

The obvious difficulties entailed in the investigation of such fetal functions limit the subject matter to a great extent. Yet it was astonishing to one not

intimately associated with such research, to find how much practical knowledge is actually at hand. The author has gathered together his material in a concise and logical manner, has added to it his own considerable number of observations, and has discussed controversial points in a constrained and enlightening manner. At the same time the book makes interesting reading and is not sifted. His is a timely subject which together with similar work on fetal pathology should speed the time when shall consider a diagnosis of death from prematurity entirely inadequate. More information of this sort should help the pediatricist to understand better and to treat more successfully many common problems of the newly born, such as asphyxia and cyanotic attacks.

In one respect, however, the reviewer found himself unsatisfied. At the end of each chapter he felt a great curiosity to know just what Dr. Windle thought about the practical implications of his research. This feeling is mentioned not at all in criticism, but in the hope that future editions may be enriched by his seasoned judgment on the many questions which come to mind. This sort of correlation between research and clinical needs is nowhere more essential than in the care of the premature and newly born infant. This volume should be "must reading" for pediatricists as well as for students and investigators in the field. C. ANDERSON ALDRICH.

PHYSIOLOGY OF THE FETUS, ORIGIN AND EXPEND OF FUNCTION IN PRENATAL LIFE. By William Frederick Windle. Philadelphia and London: Saunders Co. 1920.

CORRESPONDENCE

RADICAL CURE OF HYDROCELE BY EXCISION OF SEROUS LAYER OF SAC

TO THE EDITOR: In the issue of *SURGERY GYNECOLOGY AND OBSTETRICS* for April, 1920, a new operation for the radical cure of hydrocele by excision of the serous layer of the sac is described by Hugh Young, of Baltimore.

I have been doing this operation in Madras and now in Delhi for about six years. It is the routine

radical operation which I have practised and taught to my students for that time. I am sure Dr. Young

will be interested to know this and at the same time excuse the liberty which I take in pointing it out. I do so in no critical spirit remembering that hemorrhage probably drove me to get down to the serous layer.

OBSERVATIONS ON THE PATHOLOGY OF EXPERIMENTAL TRAUMATIC SHOCK

J ENGLEBERT DUNPHY, M D, JOHN G GIBSON, II, M D,
Boston, Massachusetts

JOHN L KEELEY, M D, New Orleans, Louisiana

AN essential feature of the shock syndrome is a disparity between the amount of circulating blood and the size of the vascular bed (1, 5, 14, 17)

In traumatic shock, this disparity is the result of a marked reduction of the blood volume as a result of a loss of fluid from the circulation into the tissues. However, except in instances of frank hemorrhage, there is still considerable disagreement as to the actual site of this loss of fluid. Some investigators maintain that it is largely confined to the site of injury whereas others hold that, as a consequence of generalized capillary injury, there is a stasis of fluid and loss of plasma throughout the body, particularly marked in the splanchnic area. In the present study an attempt is made to throw further light on this problem by correlating more closely the physiological with the pathological changes in traumatic shock.

In keeping with the concept of generalized capillary injury as a principal factor in the shock syndrome are the extensive studies of Moon and his associates on the pathological changes in shock (11-14). These investigators find as an invariable accompaniment of shock,

regardless of cause, "marked diffuse congestion of the capillaries and venules in visceral areas, especially the lungs, liver, kidneys, and the serous and mucous surfaces, edema, effusions into serous cavities and capillary hemorrhages" (12). The pathological changes are interpreted as evidence that the marked reduction of the blood volume is due to a loss of plasma and stasis of fluid throughout the viscera, particularly in the lungs, liver, and gastro-intestinal tract. Moon's investigations have done much to revive the theory of a traumatic toxemia in shock and are considered to be evidence against the idea of Blalock and others that in traumatic shock loss of fluid at the site of injury is a principal factor in the reduction of the blood volume (2, 3, 4, 9, 10, 15, 16).

Although Moon's observations clearly demonstrated that certain pathological changes may accompany shock, the causal relationship between these changes and the reduction of the blood volume was not shown. It seemed possible that in traumatic shock the primary mechanism was a loss of fluid, not blood, at the site of injury with an initial reduction of the blood volume, and that the generalized capillary change was a phenomenon secondary to the reduction of the blood volume. To determine this point, traumatic shock was

produced in animals and complete pathological examination of the viscera was made in different animals at varying intervals during the development of the shock syndrome as evidenced by determination of the blood volume, plasma volume, hematocrit and blood pressure.

EXPERIMENTAL PROCEDURE

The experimental procedure was as follows: Large mongrel dogs weighing between 18 and 28 kilograms, were used in all the experi-

ments. Shock was induced either by severe burns or by trauma to the left hind limb. Animals were allowed water but no food for 3 hours before the experiment. Anesthesia was induced by the intravenous injection of sodium pentobarbital in doses of 32 milligram per kilogram of body weight and maintained by small supplementary injections throughout the experimental period. Determinations of the blood pressure, pulse, respiration, hematocrit, plasma, and total blood volumes were made before and at varying intervals after the

Fig 1 The course of the changes in hematocrit, blood pressure, plasma and total blood volumes in an animal following severe thermal trauma

injury The plasma and blood volumes were determined by the direct method of Gibson and Evans The blood pressure was recorded on a Harvard kymograph by means of a cannula in the right femoral artery Three animals were subjected to mechanical trauma to the left hind limb, administered with a heavy padded hammer in such a manner as to avoid fracturing bones or rupturing large blood vessels Nine animals were subjected to thermal trauma by means of a Bunsen burner applied for periods of 5 to 20 minutes to shaven areas over the thorax and abdomen, constituting approximately one-third of the surface area of the animal's body As soon as the experiment was terminated, a complete postmortem examination was performed and sections of the thoracic and abdominal viscera were taken for microscopic study From all but 3 of the animals (Exp 12, 17, 18) the spleen was removed several weeks before the experiment This was done because previous observations indicated that shock could be produced more readily and more uniformly in the splenectomized dog (10)

Since the changes in the hematocrit, blood pressure, plasma, and total blood volume were quite uniform (Table I), one of the experiments is illustrative (Fig 1) It will be noted that within a few hours of the injury there is marked hemoconcentration Although the plasma blood volume is reduced to nearly two-thirds of its original total, the blood pressure is maintained well above so called "shock

levels" At this early stage of shock, when the blood volume was markedly reduced but the blood pressure was well maintained, the experiment was terminated in 5 instances (Exp 11, 12, 16, 17, 18) by the injection of a lethal dose of the anesthetic The course of an experiment which was so terminated is shown in Figure 2 This animal was subjected to repeated trauma to the left hind limb The rise in the hematocrit is an indication of shock rather than hemorrhage The details of one experiment in which the animal was sacrificed in the early stages of shock are shown in Table II

Fig 2 The course of the changes in hematocrit, blood pressure, plasma, and total blood volume following mechanical trauma to the left hind limb The experiment was terminated by a lethal dose of the anesthetic The viscera of this animal are shown in Figure 5

Pathological examination. There is cyanosis, swelling, edema and hemorrhage into the tissues of the left leg. The tissues of the abdominal wall appear normal. The peritoneal cavity contains no fluid, but the peritoneal surfaces are moist. The intestinal tract is pale and contracted. The lungs are pink and well perfused. The heart is small and contracted. It contains a moderate amount of blood. No abnormalities are noted in the gross examination of the abdominal viscera (Fig 5). Microscopically no evidence of generalized capillary damage is found.

THE PATHOLOGY OF EARLY SHOCK

Autopsy of animals sacrificed in the early stages of shock revealed marked loss of plasma and fluid at the site of injury but little or no evidence of generalized capillary injury or loss of fluid in the visceral area (Figs. 3, 4, 5). Gross inspection of the viscera showed no significant variation from the normal. There was no free fluid in the pleural or peritoneal cavities and the serous surfaces were dry. The heart appeared normal grossly and contained a moderate amount of blood. The lungs were a light pinkish yellow and were dry and crepitant throughout. The liver and kidneys showed no gross variation from the normal. The spleen in the 3 animals in which it had not been removed prior to the experiment, was contracted and firm. The cut surface was dry and little pulp could be scraped off with a knife. The gastro-intestinal tract was often pale contracted and ischemic in appearance (Fig. 4). There was no increase present in the weight of the lungs, the liver or the kidneys.

Histologically these observations were substantiated. In the lung (Fig. 6) there was no edema, extravasation of red blood cells or leukocytes, or marked engorgement of the alveolar capillaries. In scattered areas there was slight dilatation of capillaries and occasionally polymorphonuclear leucocyte infiltration of the interstitial tissue was found a change which was quite marked in the late stages of shock. The liver showed no significant variation from normal (Fig. 7). There was no engorgement of the sinusoids, necrosis of the cord cells, capillary hemorrhage or edema. A moderate number of the cord cells contained fat droplets. The gastro-intestinal tract was singularly free from edema, congestion, submucosal hemorrhages, or engorgement of the serosal vessels. There was no gross or microscopic congestion of the mesentery. The mucosa of the gastro-intestinal tract was well preserved (Fig. 8). Thus, in the initial stage of shock the changes in the viscera were more suggestive of hemorrhage than of what has been described as being typical of shock. The

Fig 3 Photograph of the viscera of an animal 4 hours after thermal trauma. The lungs were prevented from collapsing by clamping off the trachea before opening the chest. There is no visceral congestion or effusion of fluid into serous cavities. The omentum is bloodless, and small bowel is pale and contracted. The spleen had been removed.

Fig 4 Photograph of the viscera of an animal 5 hours after thermal trauma. Note that after the chest has been opened the lungs are completely collapsed against the chest wall. There is no congestion or edema of the lungs present nor is there any effusion into the pleural cavities (Exp 12).

kidney was an exception. Although the extreme degrees of congestion described by Moon were not observed, there was slight hyperemia and congestion of the glomerular capillaries even in the early stages of shock. This was particularly striking after thermal trauma, a finding which was in keeping with the fact that gross hematuria was commonly observed within a short time of the injury.

The adrenals showed no striking variation from the normal on gross examination, but microscopically there was hyperemia of the capillaries and an infiltration of polymorphonuclear leucocytes in the zona fasciculata. These changes were not marked but were present in all the dogs of the series. They developed before there was evidence of generalized capillary congestion and engorgement of ves-

sels throughout the viscera. In fact, at this stage the adjacent zona glomerulosa, zona reticularis, and medulla of the adrenal appeared quite normal despite the pathological changes in the zona fasciculata. In a previous study it was shown that these changes develop in the transplanted adrenal gland and hence are not of neurogenic origin (7).

The slight hyperemia of the pulmonary capillaries, the occasional infiltration of the interstitial tissue of the lung with polymorphonuclear leucocytes, the renal and the adrenal changes are interpreted as evidence that, under the conditions of our experiments, there are slight systemic tissue changes in early shock. The possible relation of these changes to the use of sodium pentobarbital as the anesthetic will be discussed later. However, re-

Fig. 5 Photograph of the viscera of an animal 4 hours after trauma to the left hind limb. The gross appearance of the viscera is not unlike that seen following hemorrhage. That this animal, as in shock, is shown by the rise in hematocrit (Fig. 6).

Regardless of cause these pathological changes are not sufficient to account for the marked reduction of the blood volume. Moreover as will be shown later they can be produced without a reduction of the blood volume. It is significant, therefore, that at this early stage of shock there was extensive swelling, edema, and extravasation of fluid at the site of injury. Furthermore, previous observations indicated that the calculated gain in fluid content of the injured area closely approximated the reduction of the blood volume (10). It is concluded that under the conditions of these experiments the principal loss of fluid in the early stages of traumatic shock is at the site of injury.

THE PATHOLOGY OF LATE SHOCK

In the experiments (Nos. 5, 6, 7, 8, 9, 10, 19) in which the animals were allowed to survive

for longer periods of time—6 to 12 hours—or until death occurred a somewhat different pathological picture was found. It is important to emphasize that inasmuch as shock depends upon the reaction of different animals to a variety of stimuli, standardization of experimental shock is difficult, and therefore the time factor in these experiments is not an absolute one. Certain animals develop the pathological changes of late shock in a shorter time than others. In general however the longer the animals survived the more striking were the generalized tissue changes. The extreme degrees of generalized capillary injury, visceral congestion, and effusion into serous cavities described by Moon were not found in any of these experiments. However microscopically there was a definite change in that direction and in less acute experiments which permitted the animals to survive for longer periods of time the changes might become more marked. The details of one experiment in which the animal was sacrificed in the later stages of shock are presented herein in Table III.

Fig. 6 Photomicrograph of the lungs of the same animal as in Figure 5. There is no edema or extra-alveolar cells or engorgement of the alveolar capillaries. Hematoxylin-eosin stain. X 200.

Gross examination of the viscera in the late stages of shock, after compensation had failed and the blood pressure had fallen, showed patchy areas of purplish discoloration in the lungs, particularly in the lower lobes. Microscopically (Fig 9) there was engorgement of the alveolar capillaries, extravasation of cells and fluid into the alveolar spaces, and infiltration of the interstitial tissues with polymorphonuclear leucocytes. No micro-organisms were demonstrated. In the gastro-intestinal tract there were varying degrees of hyperemia, submucosal hemorrhages, and occasionally ulcerations in the duodenum or jejunum. The mucosa was frequently poorly preserved and the small vessels of the bowel were markedly congested (Fig 10, 11). The liver was deep purplish red, and the cut surface was soft and friable. Fluid and blood oozed from it when it was sectioned. On microscopic examination there was found dilatation and engorgement of capillaries, congestion of the sinusoids with red blood cells, and degenerative changes in the cord cells (Fig 12). The kidneys appeared normal in size. On section, the demarcation of cortex and medulla was present, but the organ was deep purple, and a considerable amount of

Fig 7 Photomicrograph of the liver of an animal 4 hours after thermal trauma. There is a moderate number of fat droplets in the cord cells. There is no striking variation from the normal. Hemotoxylin-eosin stain $\times 425$

Fig 8 Photomicrograph of the jejunum of an animal 4 hours after thermal trauma. The epithelium is well preserved. There is no congestion, edema, or capillary hyperemia. Hemotoxylin-eosin stain $\times 425$

blood oozed from the cut surface. Microscopically, there was marked congestion of the glomerular capillaries, degenerative changes in the tubules, and extravasation of cells and engorgement of capillaries in the medulla.

The adrenals were pale white, but on section the cortex showed a reddish colored radial streaking as a result of hemorrhages. Microscopically there was swelling of the cortical cells in the zona fasciculata and a heavy infiltration of polymorphonuclear leucocytes. These changes were most marked in the zona fasciculata but to a lesser extent involved the zona reticularis and, in a few instances, the zona glomerulosa. There was also congestion and dilatation of the small vessels in both the cortex and medulla with occasional areas of hemorrhage. The significance of these changes

Fig. 5. Photograph of the viscera of an animal 4 hours after trauma to the left hind limb. The gross appearance of the viscera is not unlike that seen following hemorrhage. That this animal, as in shock, is shown by the rise in hematoctrit (Fig. 1).

Regardless of cause, these pathological changes are not sufficient to account for the marked reduction of the blood volume. Moreover, as will be shown later, they can be produced without a reduction of the blood volume. It is significant, therefore, that at this early stage of shock there was extensive swelling, edema, and extravasation of fluid at the site of injury. Furthermore, previous observations indicated that the calculated gain in fluid content of the injured area closely approximated the reduction of the blood volume (10). It is concluded that under the conditions of these experiments the principal loss of fluid in the early stages of traumatic shock is at the site of injury.

THE PATHOLOGY OF LATE SHOCK

In the experiments (Nos. 5, 6, 7, 8, 9, 10, 19) in which the animals were allowed to survive

for longer periods of time—6 to 12 hours—or until death occurred, a somewhat different pathological picture was found. It is important to emphasize that inasmuch as shock depends upon the reaction of different animals to a variety of stimuli, standardization of experimental shock is difficult, and therefore the time factor in these experiments is not an absolute one. Certain animals develop the pathological changes of late shock in a shorter time than others. In general, however, the longer the animals survived, the more striking were the generalized tissue changes. The extreme degrees of generalized capillary injury, visceral congestion, and effusion into serous cavities described by Moon were not found in any of these experiments. However, microscopically, there was a definite change in that direction and in less acute experiments which permitted the animals to survive for longer periods of time, the changes might become more marked. The details of one experiment in which the animal was sacrificed in the later stages of shock are presented herein in Table III.

4.15 p.m.	130	210	26	1445 c.cm	675	57	
6.15 p.m.							Animal sacrificed by intravenous injection of 10 c.cm of sodium pentobarbital.

Pathological examination disclosed extensive loss of fluid at the site of injury. Gross examination of the viscera showed no striking evidence of generalized capillary injury but on microscopic examination the changes described in detail in the text were evident.

PENTOBARBITAL SODIUM ANESTHESIA AND THE PATHOLOGICAL CHANGES IN SHOCK

It may be argued that sodium pentobarbital is shock producing and that the reduction of the blood volume and the pathological changes encountered in these experiments are the result of using this agent as an anesthetic. There is no doubt that repeated and prolonged use of the barbiturates produces capillary damage (12). The fact that this agent was used as the anesthetic and that in the early stages of shock little or no evidence of generalized capillary injury was found strengthens our contention that the initial reduction of the blood volume is due principally to a loss of fluid at the site of injury. In the late stages of shock the use of sodium pentobarbital probably plays a rôle in the development of generalized capillary injury, and the degree of shock is probably more severe than would be encountered from the injury alone.

However, control experiments have shown that the anesthetic is not the principal factor in the production of either the pathological changes or the lowered blood volume. Four dogs were subjected to sodium pentobarbital

anesthesia alone for periods of 4 to 16 hours. The physiological changes produced by this agent in a period of 7 hours are shown in Figure 13. Note that there is slight hemoconcentration and an increase in the total blood volume, but the plasma volume remains remarkably constant throughout the experimental period. The increase in the red cell volume is probably due to contraction of the spleen (10). Pathological examination of animals subjected to the anesthetic alone disclosed, in the early stages, that is, within 3 to 4 hours, comparatively little variation from the normal. There was moderate congestion of small and medium sized arteries and veins, and the intestines in two of the experiments had a somewhat dusky hue. The appearance of the bowel contrasted markedly with that seen following trauma. On microscopic examination there was found slight dilatation of vessels in the lungs, kidneys, and adrenals, and in the last mentioned a light infiltration of the zona reticularis with polymorphonuclear leucocytes. This was much less than that seen in the early stage of shock. In other words, the combination of the anesthetic and trauma

Fig. 9. Photomicrograph of the lung of an animal 15 hours after severe burn. There is marked congestion of the alveolar capillaries and extravasation of cells and fluid into the alveolar spaces. Hemotoxylin-eosin stain. $\times 200$.

in the adrenal gland is not clear and their relationship to the shock syndrome is not established. As will be described later, such changes can be produced by the anesthesia alone with out a significant reduction of the blood volume.

Fig. 10. Photomicrograph of the stomach of an animal 15 hours after thermal trauma showing extensive engorgement of capillaries and small vessels with red blood cells. Hemotoxylin-eosin stain. $\times 3$.

Fig. 11. Photomicrograph of specimen of tissue removed from the jejunum of an animal 15 hours after the administration of thermal trauma. There is present marked engorgement of the small blood vessels and capillaries. Hemotoxylin-eosin stain. $\times 425$.

than are red blood cells. This would seem to be the principal factor in initiating the reduction of the blood volume and the hemoconcentration. In the late stages of traumatic shock, either as a consequence of prolonged ischemia, adrenal insufficiency, the absorption of hypothetical toxins or factors not yet considered, there develops generalized capillary injury and loss of fluid throughout the viscera, particularly marked in the lungs, liver, kidneys, and gastro-intestinal tract. Thus, the final pathological picture is quite similar to that seen following poisoning, infection, anaphylactic shock, and other states in which capillary injury occurs.

If the late changes of traumatic shock are due solely to ischemia as a compensatory reaction to the reduced blood volume, it should be possible to prevent them by maintaining the blood volume at normal limits throughout the experimental period. This has been accomplished in a study of replacement therapy in experimental shock. The results will be reported in detail in a later publication (6). It can be briefly stated here, however, that plasma appears to be the most effective form of fluid replacement in traumatic shock, not only in restoring the blood volume to normal but also in ameliorating the late pathological changes of shock.

SUMMARY

Under the conditions of these experiments in which shock has been produced by thermal and mechanical trauma the principal factor in initiating the reduction of the blood volume is, as Blalock has long maintained, a loss of fluid at the site of injury. In late traumatic shock there is pathological evidence of generalized capillary injury and loss of fluid throughout

the viscera. This appears to be a secondary rather than a primary phenomenon.

The authors are indebted to Dr Orville Bailey, department of pathology, Harvard Medical School, for the photomicrographs.

Fig. 3. The course of the changes in the hemocrit, blood pressure, plasma, and total blood volume following the administration of sodium pentobarbital—3 mgm. per kg. of body weight. There is hemoconcentration in keeping with the increase in the total blood volume but no reduction of the plasma volume. The increase in the red cell volume is due to contraction of the spleen.

produced more striking changes in the adrenal than was observed after the anesthetic alone. The gastro-intestinal tract and liver showed no variation from the normal. After longer administration of the sodium pentobarbital 8 to 10 hours, the changes in the lungs, kidneys and adrenals were more striking but there was still no evidence of generalized capillary injury in the other viscera. With large doses over a sufficiently long period of time the late changes of shock can be produced by the barbiturates as well as by a variety of other toxic agents (12).

It is concluded that under the conditions of these experiments the use of sodium pentobarbital as the anesthetic plays no significant role in the early and marked reduction of the blood volume that the anesthetic alone is capable of producing pathological changes in the adrenals, lungs and kidneys similar to those described but that these changes are less marked than those observed when the anesthetic is followed by mechanical or thermal trauma that the changes in the gastro-intestinal tract are not attributable to the anesthetic in the doses used as they were not observed in the control experiments and finally that since it is a toxic agent and known to cause capillary damage the administration of sodium pentobarbital probably accentuates the late patho-

logical changes which have been observed in these experiments.

However the use of sodium pentobarbital does not alter the principal contention of this study namely that in the early stages of traumatic shock there is comparatively little evidence of generalized capillary injury whereas there is obvious and marked loss of fluid at the site of injury.

EVALUATION OF STUDY

Although it is generally accepted that a reduction of the effective blood volume is a constant finding in shock, the physiological and pathological mechanisms by which this is brought about are dependent largely upon the causative factors, and hence may differ widely. Shock may thus be regarded as the end result of a variety of pathological and physiological processes. Thus in anaphylactic shock, certain forms of poisoning, infection, and histamine intoxication it is likely that the primary mechanism is generalized capillary injury. This not only increases the size of the vascular bed, thus bringing about a relative reduction of the effective blood volume but eventually as a consequence of loss of fluid and plasma throughout the viscera, produces an actual reduction of the blood volume with hemoconcentration. Histological studies in this form of shock reveal evidence of loss of fluid and cells throughout the viscera (12). On the other hand, in shock due to hemorrhage the primary mechanism is a loss of whole blood from the circulation. There is a compensatory vasoconstriction. Postmortem examination discloses only generalized ischemia of the viscera. If death is not immediate, however and the animal is kept in a state of shock by repeated small hemorrhages, eventually as Blalock (4) has shown, there is evidence of generalized capillary injury and loss of fluids in the viscera. This generalized capillary injury may be the result of prolonged vasoconstriction with consequent ischemia of the viscera.

The present study indicates that in traumatic shock the early physiological and pathological mechanisms are similar to those in shock resulting from hemorrhage except that fluid and plasma are lost in higher proportion

pyloric obstruction due to gastric carcinoma. For 2 weeks previous to his admission there had been some vomiting and roentgen-ray examination showed a fair degree of pyloric obstruction. Clinically he showed signs of mild dehydration and loss of weight. In this case the test showed a shortened disappearance time with the mild dehydration and an increase toward normal as fluids were provided. This is precisely the finding one would expect if the test was a good indicator of the state of hydration, as suggested by Hopps and Chris-

topher. However, this was not found to be a constant feature in any of the other cases examined.

Table V shows the data for patient C B who had a cholecystectomy and choledochostomy for a common duct stone with obstructive jaundice. Her postoperative course was essentially uneventful, the jaundice cleared completely and her general condition was good at the time the test was started on January 4, the nineteenth postoperative day. This patient was allowed to dehydrate for the

THE McCURE-ALDRICH TEST IN WATER BALANCE

DUGALD S. MCINTYRE, M.D. SVEND PEDERSEN Ph.D. and
WALTER G. MADDOCK, M.D. F.A.C.S. Ann Arbor Michigan

THE intradermal salt solution test was introduced in 1923 by McClure and Aldrich (1, 17) as "of value in determining the so called pre-edematous state of the tissues in nephritis. It has been extensively studied since then in relation to edema (10, 11, 14, 20) fevers, (4, 5, 12) toxemia of pregnancy (15) thyrotoxicosis (9, 18) and jaundice (19). In 1927 Appel and Brill (2) first proposed its use in estimating the state of hydration of patients. Recently Hopps and Christopher (13) employed the test in following the postoperative water balance of 7 surgical patients and stated that it was a sensitive and reliable index of the degree of hydration provided that the electrolyte balance had been taken into consideration. Our experience has not substantiated this opinion.

CONTROLLED DEHYDRATION STUDY

In the course of previous investigations in this laboratory on the water exchange of surgical patients, dehydration was produced in two normal individuals by limiting their water intake. Both subjects received an adequate maintenance diet of low water content, the mineral content was essentially constant. The full details of this experiment have been published previously (8) with the exception of the McClure Aldrich tests which are reported at this time.

The technique which was used in performing the test was the same as described by the originators: 0.2 cubic centimeter of an 0.8 per cent saline solution was injected intradermally at the volar surface of a forearm and the anterior surface of a leg. Table I shows the water balance and McClure Aldrich tests of subject J. N. Table II the same for subject R. M. Contrary to the expectations of Hopps and Christopher and others (16) who look for a more rapid disappearance of the wheal with

dehydration more time was needed for these two normal subjects to absorb the salt solution when dehydration was present than for the preliminary hydrated period. Furthermore, no consistent reduction in the disappearance time occurred in the recovery period.

STUDIES ON NORMAL INDIVIDUALS

White and Irvine Jones have emphasized the variations in the disappearance time of the McClure-Aldrich test in normal individuals. In addition, Wohl and Ettelson reported that there were wide variations in fat individuals in different areas at the same time. Our subject J. N. also showed considerable differences between the disappearance times on the forearm and the leg. To learn more of these differences at first hand a series of the tests were run on 5 patients with local lesions but in good general health, who were taking a full general diet and as much water as they pleased. Table III shows the findings in these cases. It will be noted that wide variations occurred between the disappearance times in different individuals, between the different locations on the same subject, and between successive days in the same location on the same individuals. As much as a 40 minute variation was occasionally found between the tests.

STUDIES ON SICK SURGICAL PATIENTS

A series of carefully controlled studies of the water and electrolyte balance of sick surgical patients was next carried out in the hope that, in spite of the wide variations found in normals, the McClure Aldrich test might show significant variations associated with changes in either the water balance or the plasma chemistry which would be of clinical value. A few of the most representative cases are herein reported.

Table IV shows the water balance, plasma chemistry studies and McClure-Aldrich tests on patient C. D. a 64 year old man with

From the Department of Surgery of the University of Michigan. Assisted by grants from the Horace H. Rackham School of Graduate Studies.

take intravenously to replace her fluid and electrolyte losses and at the end of this 24 hours she was well hydrated, her weight was within a kilogram of the original, but the average of the skin tests was only 40.5 minutes, which was 25 minutes less than the starting values. Summarizing this case there were discrepancies in the relationship between the degree of hydration and the McClure-Aldrich test which seemed to make the latter unreliable.

Table VI shows the data for a 63 year old male with pyonephrosis and uremia. On admission he was comatose and showed signs of marked dehydration and acidosis. The general examination was otherwise essentially negative except for the urine which was found to be loaded with red and white blood cells and a mixed bacillary and coccal infection.

An examination of Table VI shows that the situation is a complicated one, the carbon-dioxide combining power remained below normal throughout the study, the plasma chlorides decreased in the 4 days from 521 to 431 milligrams per cent, considerable sodium chloride was excreted in the urine daily, the urine output was high, yet on January 7 there was a gain of 2.3 kilograms which, since his caloric intake was insufficient, must have been due to water and salt retention. In spite of all these variations the McClure-Aldrich test on January 5, the beginning of the study, was not much different from that on January 8, the end of the study, and one can deduce little from it in relation to the rest of the findings.

The next case, Table VII, is that of a 33 year old female who on admission was mark-

next 2 days by limiting the fluid intake to 500 cubic centimeters of water by mouth daily. After the January 5 period when she had lost 2661 grams in weight the average of the McClure Aldrich tests showed a rise to 77 minutes from 66 minutes. On January 6 the weight decrease was 1339 grams and the McClure Aldrich test dropped to an average of 45.5 minutes which according to Hopps and Christopher would be an indication of de

hydration. On January 7 when replacement therapy was largely given intravenously the McClure Aldrich test approached the normal. On January 8 the patient was allowed to take only what she wished to eat and drink with the result that her intake was not adequate and she voided only 200 cubic centimeters of urine. At the end of this period the skin test showed a drop to an average of 42.3 minutes. The patient was again given an adequate in-

†Given before test started

edly dehydrated. Although the history was unreliable it was felt that the patient most probably had had ergot poisoning due to drug therapy 9 months previous to admission. A left midhigh amputation for gangrene of the left leg had been done, and on admission there was gangrene of the right great toe and of the right middle finger. No wrist pulsations could be felt but her circulation showed no evidence of impairment above the elbows. With the hydration of the first 24 hours the patient gained 3.7 kilograms and the plasma chlorides increased approximately 100 milligrams per cent to reach a level close to normal. The urine output was good and sodium chloride was excreted by the kidneys. In spite of this the time for the McClure Aldrich tests was

far below normal before treatment was given and remained so after hydration. Cohen and his co-workers (6, 7, 21) showed that there was more rapid absorption of the intradermal salt wheal in areas with disturbed peripheral circulation and this condition may have been present on the forearms but there was no indication of disturbed circulation in the shoulder region where far below normal readings persisted. There was no apparent significance of the McClure Aldrich test in relation to the water and electrolyte balance of this patient.

SUMMARY

Although Appel working with Brill in 1927 (2) first advocated the use of the McClure Aldrich test as an index of water metabolism

THE VENOUS CIRCULATION IN THE LOWER EXTREMITIES DURING PREGNANCY

J ROSS VEAL, M D, F A C S, and HUGH HUDSON HUSSEY, M D,
Washington, District of Columbia

LOCAL disturbances in the venous circulation of the lower extremities are quite common both during and immediately following pregnancy. Such disturbances are manifested by the development of varicose veins or the aggravation of varicosities already present, by the appearance of edema in which cardiac, renal, nutritional, or endocrine causes are obviously lacking, and by the occurrence of acute thrombophlebitis, usually as a postpartum complication.

That the state of being pregnant is influential in the production of edema and varicose veins in the lower extremities is generally recognized. The mechanism responsible for these symptoms, however, has never been clearly demonstrated. The symptoms are entirely absent in many patients, are mild in others, and are severe in still others. That some anatomical or physiological factor or "peculiar predisposition" exists in some pregnant women but not in others is suggested by the variability of time of onset, extent, and course of the edema and varicose veins. Since such manifestations are common complications of pregnancy in all races and all classes it does not seem logical to assume the existence of any "peculiar predisposition," such as congenital weakness of the valves of the venous system.

Certain physiological changes occur during pregnancy that might alter the venous circulation in the lower extremities. It is generally accepted that there is an increase in the total blood volume. There is also an increase locally in the volume of blood in the pelvic veins. This is due partly to the augmented vascular supply incident to growth of the uterus and partly to the formation of arterio-

venous communications in the placenta. These physiological changes are found in every pregnancy and consequently do not explain the variability of occurrence of varicose veins and edema. Furthermore, such changes are hardly of sufficient magnitude to account for these symptoms in any case.

Changes in the anatomy of the pelvic organs during pregnancy produce considerable obstruction to the venous return from the lower extremities. Furthermore, the anatomical changes are variable. The position and size of the uterus, the length and mobility of the supporting ligaments, the size of the pelvis, and the tone and development of the abdominal muscles, all may vary to some degree in different pregnant women. Such anatomical variations may account for differences in the degree of obstruction to the outflow of blood from the lower extremities. In some women the obstruction may be sufficient to produce varicose veins and edema.

If obstruction of the femoro-iliac veins is the principal factor in the pathogenesis of edema and varicose veins in pregnant women, it is logical that the most direct approach to the early detection of these disturbances might be by measurements of the blood pressures in the veins of the lower extremities. It seems probable also that such measurements might yield a more complete explanation for the clinical inconsistency of varicose veins and edema in pregnant women. Burwell has demonstrated that the pressures in the femoral veins recorded with the patients in the supine position increase progressively during pregnancy, without any significant change in the venous pressures in the upper extremities, and that delivery is followed by prompt restoration of the pressures to normal. We have confirmed these findings. However, the height of the femoral venous pressure recorded with the patient lying down cannot be correlated

so that the zero level of the column of mercury is on a plane with the point at which the venipuncture is to be made. This adjustment is accomplished by means of a carpenter's level. The patient is instructed in the procedure of the test and is shown how to perform the exercise. She stands erect, with feet slightly apart, on a smooth table set against the wall, where supports are provided for her hands. The lower half of the thighs and the legs are exposed, shoes and stockings being removed. Standing behind the patient, the operator palpates the lower border of the patella with his index finger, and locates with the thumb of the same hand a point on this same level and just medial to the lateral head of the gastrocnemius and the plantaris muscles. After appropriate sterilization of the skin, a wheal is produced at this point with 1 per cent solution of novocain. A 19 gauge, $1\frac{1}{2}$ inch needle, attached to a 5 cubic centimeter syringe is inserted through the anesthetized area and is pushed straight forward until the popliteal vein is punctured. During the insertion of the needle, traction is exerted upon the plunger of the syringe so that entrance of the needle into the vein can be instantly recognized by the spurt of dark red blood into the syringe. The depth to which the needle must be inserted varies somewhat in different individuals but usually is about 2.5 centimeters. The patient is warned that she may experience a shock of pain radiating down her leg. She is cautioned not to move this leg but to inform the operator of the discomfort. This happens not infrequently and is caused by pricking the tibial nerve which lies close to the lateral surface of the vein. The pain is only momentary and guides the operator for reinsertion of the needle slightly more medially. When the popliteal vein has been entered the syringe is detached from the needle, and the adaptor of the venous pressure apparatus is connected to the needle. Loss of a small amount of blood is unavoidable during this transfer. Finally, the clamp is removed from the tubing of the apparatus.

The column of mercury in the manometer will quickly come to a level which indicates the local blood pressure in the vein. The height of this level is recorded as the initial

Fig. 1. Mercury U tube for measurement of popliteal venous pressure. Connection to popliteal vein through closed system.

venous pressure. The patient then begins the exercise which consists in rising on her toes repeatedly (20 to 30 times) for 1 minute. It is important that she use the wall supports for her hands only for the purpose of steadying herself and not as a means of assisting the exertion, that she breathe regularly during the exercise, and that she relax the muscles of her legs each time her heels are lowered to the surface of the table. During the test it is necessary for the operator to support the rubber tubing of the apparatus with his hand in order to keep the needle horizontal and prevent it from slipping. The changes in venous pressure during exercise are recorded, and the pressure is observed for a short time after exercise has ceased. The needle is then withdrawn and firm pressure is applied for about a minute at the site of venipuncture. The patient is required to walk around the room for a few minutes at the conclusion of the test in order to prevent venous thrombosis.

In normal individuals and in patients with edema of the lower extremities due to nephrosis, nutritional deficiency, or lymphatic ob-

with the occurrence of varicose veins and edema. Thus patients with marked edema and varicose veins may have lower femoral pressures recorded in this way than some patients who have neither of these symptoms, so that confirmation of venous obstruction as the cause of the symptoms is not obtained.

As far as we have been able to discover from reviewing the literature no attempt has previously been made to measure the pressures in the deep veins of the lower extremities of pregnant women with the patients standing. It must be recognized that such a procedure might elicit evidence of venous obstruction that would be lacking in venous pressure measurements obtained in the usual way. This presumption is based upon the fact that the upright posture apparently aggravates the manifestations of obstruction of the veins in susceptible patients. Furthermore, in patients with edema rest in bed usually relieves the edema, and if varicose veins are present these promptly collapse. For measurement of venous pressures in the lower extremities with patients standing deep veins must be used for accurate results. The pressures in the superficial veins are much too readily influenced by local factors, such as muscular exercise and tone, the state of the veins and the venous valves etc. For reasons that will be obvious later the popliteal vein is most suitable for the purpose in view.

Unfortunately a single measurement of the pressure in the popliteal vein with the patient standing is impossible of interpretation by ordinary means. Only the local pressure (pressure at the level at which the vein is punctured) can be estimated. The reference point for the zero level of the manometer for measurement of the pressure in terms which take into account the hydrostatic pressure is unknown. Even in the absence of localized venous obstruction the local popliteal pressure shows a great and as yet unaccountable variation in different patients. Repeated measurements of the local pressure in the popliteal vein in a pregnant woman might be useful for demonstrating progression of venous obstruction but even this is doubtful. It has been our experience in previous studies (3, 4) that there is no constant relationship

between venous obstruction and the height of the venous pressure measured in the usual way. This is due to the fact that obstruction of the peripheral veins leads to the development of collateral channels which often are adequate to carry away the blood under resting conditions, so that the venous pressure may remain relatively normal. In such cases, however exercise imposes conditions in which the venous collateral circulation may be quite inadequate. For example exercise of an extremity in which the veins are partially obstructed may augment the inflow of arterial blood many times what it is during rest. Then the venous pressure in the affected extremity will rise to a varying degree, depending on the amount of venous obstruction and the extent of the collateral circulation, although it may have been within the normal range before exercise began. These facts led us to devise means for measuring the venous blood pressure during standard exercise tests in patients suspected of having obstruction of the veins of the upper or lower extremity.

The exercise test of venous pressure in the lower extremity entails the use of the popliteal vein. The apparatus (Fig. 1) for measurement of popliteal venous pressure consists of a mercury U tube manometer one arm of which is straight the other arm bent at an angle to facilitate attachment of a piece of rubber tubing. A millimeter scale is affixed beside the straight arm for purposes of recording pressures. Measurements obtained on this scale of course must be doubled in order to represent true records of pressures in terms of millimeters of mercury. The other arm is filled completely from the surface of the column of mercury to its tip with 2.5 per cent sodium citrate solution. The height of the column of mercury beside the millimeter scale is noted. Next a sterile length of rubber catheter tubing having a needle adaptor in one end is filled completely by means of a sterile 5 cubic centimeter syringe with sterile 2.5 per cent sodium citrate solution. This tubing is clamped with a small hemostat and its free end is then slipped on the designated arm of the manometer care being taken to exclude air bubbles from the system. The manometer is adjusted on its supporting stand

so that the zero level of the column of mercury is on a plane with the point at which the venipuncture is to be made. This adjustment is accomplished by means of a carpenter's level. The patient is instructed in the procedure of the test and is shown how to perform the exercise. She stands erect, with feet slightly apart, on a smooth table set against the wall, where supports are provided for her hands. The lower half of the thighs and the legs are exposed, shoes and stockings being removed. Standing behind the patient, the operator palpates the lower border of the patella with his index finger, and locates with the thumb of the same hand a point on this same level and just medial to the lateral head of the gastrocnemius and the plantaris muscles. After appropriate sterilization of the skin, a wheal is produced at this point with 1 per cent solution of novocain. A 19 gauge, $1\frac{1}{2}$ inch needle, attached to a 5 cubic centimeter syringe is inserted through the anesthetized area and is pushed straight forward until the popliteal vein is punctured. During the insertion of the needle, traction is exerted upon the plunger of the syringe so that entrance of the needle into the vein can be instantly recognized by the spurt of dark red blood into the syringe. The depth to which the needle must be inserted varies somewhat in different individuals but usually is about 2.5 centimeters. The patient is warned that she may experience a shock of pain radiating down her leg. She is cautioned not to move this leg but to inform the operator of the discomfort. This happens not infrequently and is caused by pricking the tibial nerve which lies close to the lateral surface of the vein. The pain is only momentary and guides the operator for reinsertion of the needle slightly more medially. When the popliteal vein has been entered the syringe is detached from the needle, and the adaptor of the venous pressure apparatus is connected to the needle. Loss of a small amount of blood is unavoidable during this transfer. Finally, the clamp is removed from the tubing of the apparatus.

The column of mercury in the manometer will quickly come to a level which indicates the local blood pressure in the vein. The height of this level is recorded as the initial

Fig 1 Mercury U tube for measurement of popliteal venous pressure. Connection to popliteal vein through closed system.

venous pressure. The patient then begins the exercise which consists in rising on her toes repeatedly (20 to 30 times) for 1 minute. It is important that she use the wall supports for her hands only for the purpose of steadying herself and not as a means of assisting the exertion, that she breathe regularly during the exercise, and that she relax the muscles of her legs each time her heels are lowered to the surface of the table. During the test it is necessary for the operator to support the rubber tubing of the apparatus with his hand in order to keep the needle horizontal and prevent it from slipping. The changes in venous pressure during exercise are recorded, and the pressure is observed for a short time after exercise has ceased. The needle is then withdrawn and firm pressure is applied for about a minute at the site of venipuncture. The patient is required to walk around the room for a few minutes at the conclusion of the test in order to prevent venous thrombosis.

In normal individuals and in patients with edema of the lower extremities due to nephrosis, nutritional deficiency, or lymphatic ob-

with the occurrence of varicose veins and edema. Thus patients with marked edema and varicose veins may have lower femoral pressures recorded in this way than some patients who have neither of these symptoms, so that confirmation of venous obstruction as the cause of the symptoms is not obtained.

As far as we have been able to discover from reviewing the literature, no attempt has previously been made to measure the pressures in the deep veins of the lower extremities of pregnant women with the patients standing. It must be recognized that such a procedure might elicit evidence of venous obstruction that would be lacking in venous pressure measurements obtained in the usual way. This presumption is based upon the fact that the upright posture apparently aggravates the manifestations of obstruction of the veins in susceptible patients. Furthermore in patients with edema, rest in bed usually relieves the edema and if varicose veins are present these promptly collapse. For measurement of venous pressures in the lower extremities with patients standing deep veins must be used for accurate results. The pressures in the superficial veins are much too readily influenced by local factors, such as muscular exercise and tone, the state of the veins and the venous valves, etc. For reasons that will be obvious later the popliteal vein is most suitable for the purpose in view.

Unfortunately a single measurement of the pressure in the popliteal vein with the patient standing is impossible of interpretation by ordinary means. Only the local pressure (pressure at the level at which the vein is punctured) can be estimated. The reference point for the zero level of the manometer for measurement of the pressure in terms which take into account the hydrostatic pressure is unknown. Even in the absence of localized venous obstruction the local popliteal pressure shows a great and as yet unaccountable variation in different patients. Repeated measurements of the local pressure in the popliteal vein in a pregnant woman might be useful for demonstrating progression of venous obstruction but even this is doubtful. It has been our experience in previous studies (3, 4) that there is no constant relationship

between venous obstruction and the height of the venous pressure measured in the usual way. This is due to the fact that obstruction of the peripheral veins leads to the development of collateral channels which often are adequate to carry away the blood under resting conditions, so that the venous pressure may remain relatively normal. In such cases, however, exercise imposes conditions in which the venous collateral circulation may be quite inadequate. For example, exercise of an extremity in which the veins are partially obstructed may augment the inflow of arterial blood many times what it is during rest. Then the venous pressure in the affected extremity will rise to a varying degree depending on the amount of venous obstruction and the extent of the collateral circulation, although it may have been within the normal range before exercise began. These facts led us to devise means for measuring the venous blood pressure during standard exercise tests in patients suspected of having obstruction of the veins of the upper or lower extremity.

The exercise test of venous pressure in the lower extremity entails the use of the popliteal vein. The apparatus (Fig. 1) for measurement of popliteal venous pressure consists of a mercury U-tube manometer, one arm of which is straight, the other arm bent at an angle to facilitate attachment of a piece of rubber tubing. A millimeter scale is affixed beside the straight arm for purposes of recording pressures. Measurements obtained on this scale of course must be doubled in order to represent true records of pressures in terms of millimeters of mercury. The other arm is filled completely from the surface of the column of mercury to its tip with a 2.5 per cent sodium citrate solution. The height of the column of mercury beside the millimeter scale is noted. Next a sterile length of rubber catheter tubing having a needle adaptor in one end is filled completely by means of a sterile 5 cubic centimeter syringe with sterile 2.5 per cent sodium citrate solution. This tubing is clamped with a small hemostat and its free end is then slipped on the designated arm of the manometer care being taken to exclude air bubbles from the system. The manometer is adjusted on its supporting stand

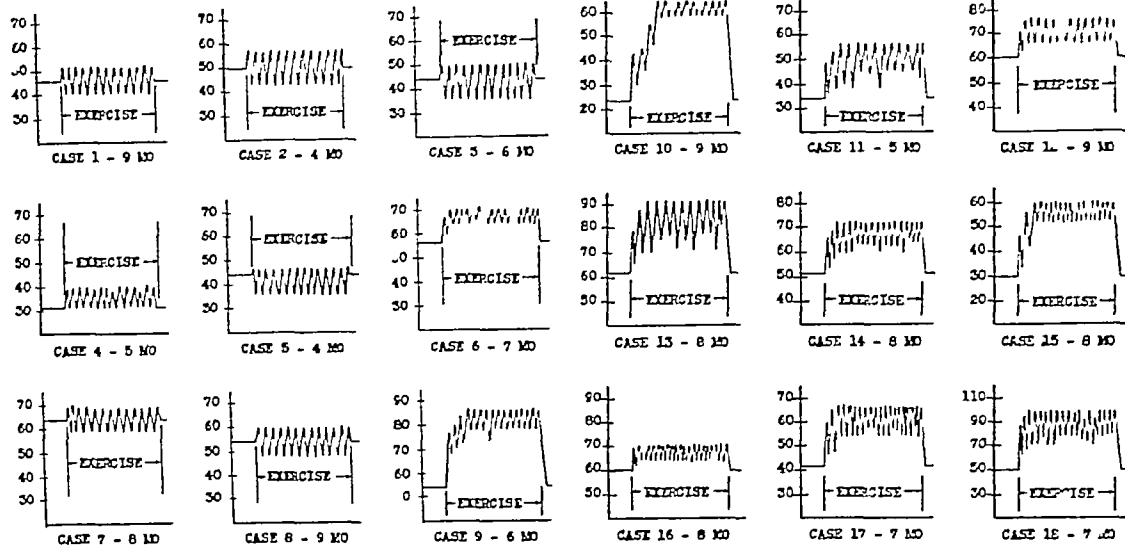

Fig 4 Popliteal venous pressures (mm of mercury) in pregnant women having no edema or varicose veins. Note the uniformity of patterns except in Cases 6 and 9.

Fig 5 Popliteal venous pressures (mm of mercury) in pregnant women having edema and/or varicose veins. Note uniformity of patterns.

while the 16 others, or 44 per cent, had edema, or varicose veins, or both. Fourteen of the women, 39 per cent, were primiparas, and 22, 61 per cent, were multiparas. Only 4 of the 14 primiparas, 29 per cent, had edema or varicose veins or both, while 12 of the 22 multiparas, 55 per cent, had these manifestations. Although the group is small, this higher incidence of such manifestations in multiparas is in keeping with the general experience of obstetric practice.

Because of the social level of the patients attending the clinic at which our studies were made, comparatively few patients were observed early in pregnancy (Fig 3). Thus only 1 of the 36 patients was in the first trimester, 10 were in the second trimester, and the 25 remaining were in the final trimester. The single case observed during the first trimester had neither edema nor varicose veins, but 15 of the 25 in the third trimester, 60 per cent, had edema and/or varicose veins. The higher incidence of these manifestations in the latter months of pregnancy again is in accord with usual obstetric experience.

In each case a recording of the initial pressure in the popliteal vein was obtained with the patient standing quiet, after which the

"exercise test" as herein described was performed. There was no immediate correlation between the initial pressures and the presence of edema or varicose veins (Fig 3). In fact, the 3 lowest initial pressures were recorded in patients with edema and varicose veins. Of the 20 patients having neither edema nor varicose veins, 18, or 90 per cent, showed normal patterns of the popliteal venous pressure during exercise. That is, the pressure fluctuated above and below the initial pressure or oscillated between the initial pressure and a reading not more than 8 millimeters of mercury above the initial pressure. Figure 4 demonstrates examples of the normal patterns obtained in these cases, except Cases 6 and 9. In these 2 cases, 10 per cent, the response of the popliteal venous pressure to exercise followed an obstructive pattern. In Case 6, after an initial reading of 56 millimeters, the venous pressure fluctuated during exercise from 64 to 70 millimeters. In Case 7, the initial reading was 54 millimeters, during exercise the pressure ranged from 68 to 86 millimeters.

In the 16 patients having edema or varicose veins or both, obstructive patterns of response of the popliteal venous pressure during exer-

struction, the popliteal venous pressure is little affected by the exercise described. The column of mercury in the manometer fluctuates usually above and below its initial level through a distance of 8 to 12 millimeters but shows no tendency to rise progressively. On the other hand, in patients having significant obstruction of the femoral or iliac veins due to thrombosis compression by tumor or other cause the popliteal venous pressure, in addition to oscillating with each movement of the patient as she performs the prescribed exercise tends to rise progressively. The amount of rise theoretically should depend mainly upon the degree to which there is delay in the outflow of blood through the obstructed veins. However it has been our experience that the pattern which can be traced from the response of the venous pressure to the exercise imposed is of more practical importance than the amount of rise. In other words a pattern which shows only oscillation of the pressure above or below the initial venous pressure indicates that the venous system is adequate under conditions

of the test while a pattern which shows a progressive rise of the pressure to any degree in addition to the same type of oscillation, indicates that the venous system is inadequate. Figure 2 presents the contrast of the two types of pattern. In this case of femoro-femoral thrombosis of the right side the popliteal venous pressures clearly demonstrate the presence of venous obstruction in the right leg and the absence of obstruction in the left leg.

It was our interest in the preparation of this present report to apply the procedure of measurement of popliteal venous pressure with the patient standing and during exercise to pregnant women as a part of the search for an explanation of the cause of varicose veins and edema.

CLINICAL RESULTS

Thirty-six pregnant women were studied in the order of their admission to the prenatal clinic in the outpatient department at the Gallinger Municipal Hospital. No attempt at case selection was made but no patient in the group had any detectable toxemia or other complicating illness. All of the patients were of the negro race. Twenty of the 36 or 56 per cent had neither edema nor varicose veins,

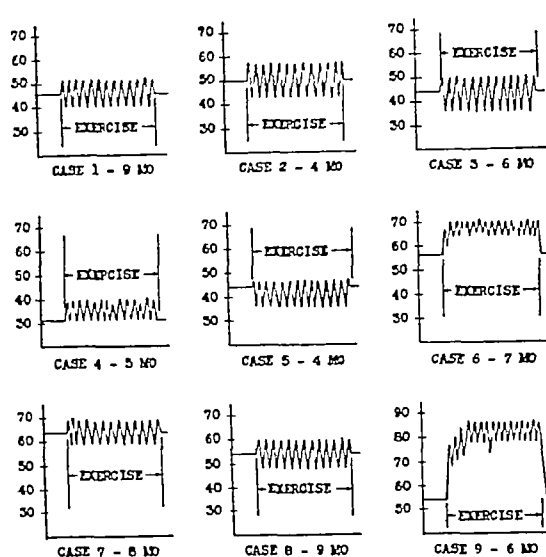

Fig 4 Popliteal venous pressures (mm of mercury) in pregnant women having no edema or varicose veins. Note the uniformity of patterns except in Cases 6 and 9

while the 16 others, or 44 per cent, had edema, or varicose veins, or both. Fourteen of the women, 39 per cent, were primiparas, and 22, 61 per cent, were multiparas. Only 4 of the 14 primiparas, 29 per cent, had edema or varicose veins or both, while 12 of the 22 multiparas, 55 per cent, had these manifestations. Although the group is small, this higher incidence of such manifestations in multiparas is in keeping with the general experience of obstetric practice.

Because of the social level of the patients attending the clinic at which our studies were made, comparatively few patients were observed early in pregnancy (Fig 3). Thus only 1 of the 36 patients was in the first trimester, 10 were in the second trimester, and the 25 remaining were in the final trimester. The single case observed during the first trimester had neither edema nor varicose veins, but 15 of the 25 in the third trimester, 60 per cent, had edema and/or varicose veins. The higher incidence of these manifestations in the latter months of pregnancy again is in accord with usual obstetric experience.

In each case a recording of the initial pressure in the popliteal vein was obtained with the patient standing quiet, after which the

cise were obtained in all cases. Figure 5 gives some examples of these patterns. In 2 of these cases (Cases 12 and 16) the fluctuations of pressure during exercise were of relatively low order possibly indicating that the venous obstruction was of milder degree. In the 14 remaining patients, patterns typical of severe venous obstruction were obtained during exercise. For example in Case 10 the fluctuations of pressure reached peaks of 40 millimeters of mercury higher than the initial pressure of 24 millimeters. In Case 5 the oscillations were 22 to 30 millimeters and in Case 18 20 to 40 millimeters higher than the initial pressure. In one other case not shown in the figure the peaks of the oscillations were 56 millimeters higher than the initial popliteal venous pressure.

EVALUATION

The assumption that postural dependent edema and varicose veins in pregnant women are due mainly to compression of the iliac veins by the enlarging uterus or as the result of other anatomical changes, has always had some clinical substantiation. However it has been difficult to reconcile with this assumption the fact that all pregnant women do not develop these manifestations. Venous pres-

ures measured in the usual manner in the femoral veins with the patients supine do not differ significantly in the group of women with supposed evidence of venous obstruction and the group without such clinical evidence. Although the complete reconciliation of these facts has not been achieved, the original assumption has been sustained by the patterns obtained by the measurement of the pressures in the popliteal veins during exercise. In addition it has been learned that in pregnant women who show varicose veins or edema of the type under discussion there actually is a more severe degree of venous obstruction than in women who are free of these symptoms. Failure of femoral venous pressure determinations of the usual type to demonstrate this difference must be ascribed to the incompleteness of the procedure. It does not take into account the facts that a venous system may be adequate during rest and grossly inadequate under conditions of ordinary activity and that an upright posture may play a large part in aggravating obstruction of the venous flow from the lower extremities.

Further clinical proof of the obstructive origin of edema and varicose veins during pregnancy is found in the occasional case in which the symptoms are strictly unilateral. For example, in one patient of the group studied there was moderate edema of the left lower extremity without edema of the right at the eighth month of pregnancy. This kind of phenomenon would be difficult to explain except as the result of obstruction of the left iliac vein and indeed the patterns obtained on measurement of the popliteal venous pressures during exercise (Fig. 6) support the clinical evidence. The pattern from the left popliteal vein is one of venous obstruction, while that from the right popliteal vein is normal. This case and the type of case in which edema or varicose veins are most prominent during the early months of pregnancy and tend to regress as pregnancy continues strongly suggest that the position of the uterus may be important in the pathogenesis of localized obstruction of the deep veins. However speculation as to the anatomical or other factors responsible for heightening the degree of occlusion of the veins in pregnant women who develop the

symptoms discussed here cannot be very fruitful in the absence of additional careful studies of the anatomy and physiology of the venous system

In our opinion, measurements of the popliteal venous pressures during exercise in pregnant women who show edema of the lower extremities yields information which is essential to the care of the patient. If the venous pressure pattern is not of the type found in cases of venous obstruction, some other cause for the edema should be sought. On the other hand, if an obstructive pattern is obtained, care of the patient should be directed to the prevention of varicose veins. One of us (2) has shown that protection of the superficial veins by means of elastic stockings will prevent or greatly minimize the development of varicose veins in patients having localized obstruction of the femoro-iliac veins. The stockings are even more useful in pregnant women than in some other cases because the duration of venous obstruction is relatively so much shorter. If the superficial veins are protected in this way, their valves remain intact and varicose veins are consequently less likely to appear.

SUMMARY AND CONCLUSION

1 The assumption that postural dependent edema and varicose veins of the lower extremities in pregnant women are due to

localized obstruction of the deep veins is supported by the types of pressure curve obtained when popliteal venous pressures are recorded during exercise

2 The factors responsible for increasing the degree of localized venous obstruction in some pregnant women to the point of causing edema or varicose veins or both are not perfectly understood. The size and position of the uterus are factors of recognized importance

3 In pregnant women manifesting significant obstruction of the femoro-iliac veins, provision of adequate support for the superficial veins by means of elastic stockings minimizes or prevents the development of varicose veins

We wish to thank the members of the Department of Obstetrics of the Gallinger Municipal Hospital for their co operation in these studies

PERSISTENCE OF FUNCTION OF SKIN GRAFTS THROUGH LONG PERIODS OF GROWTH

JAMES BARRETT BROWN, M.D., F.A.C.S., and FRANK McDOWELL, M.D.
St. Louis, Missouri

FUNCTION has been found to persist in large skin grafts that have been in place during long periods of growth and the fundamentals that have proved of value in carrying out large surface repairs are reviewed here.

Both thick split and full thickness grafts do seem to grow or at least stretch out with growth of the body area and to permit normal movement if they have been successful from the start. This has been true in many patients and over areas of the body from the face to the feet (Figs. 1 to 10).

There is a condition that may be called *generalized skin shortening* of an area in which there is no evident distortion but a definite lack of flexibility and ease of function. This may result from failure of releasing the scar sufficiently or from growth of the area without enough enlargement of original grafts. The

condition may be likened to clothes that are too tight or it may be said that the skin envelope is too small. This means that *scar and its contracture persist until released*. If it is completely released early in life the repair should last. If with increased growth, the shortening does appear then more skin can be let in by simply opening the tightest area, allowing the edges to retract and filling the resultant defect with suitable grafts. Where the scar tissue is very thick, however, the edges will not retract when opened and then large areas have to be excised down to good soft tissue and still larger grafts applied (Figs. 6 and 10).

By *satisfactory late function of the grafts* is meant (1) enough skin for free movement (2) moderate looseness (3) ability to withstand the usual trauma of getting around (4) the development of normal sensation. Full normal sensation usually develops in free skin grafts and is influenced by the amount of deep scar that is left and of course, is dependent on there being sensory nerves in the area.

Fig. Extreme deformity of neck and jaw corrected by thick split graft and full thickness graft operations. Recorded after an 8 year period of growth with complete

restoration of contour. Surface smoothness can be improved with further grafts when patient takes. Both ulcers also repaired.

Metaplasia of grafts (and flaps also) does not take place and, therefore, a really normal sole of the foot, for instance, cannot be restored. This area is specialized to the point of being an organ, the skin and subcutaneous tissues are different from birth and the peculiar bearing qualities are not developmental. A graft or a flap on a sole may make calluses (or even annoying warts) but it will not meta-plate into true skin or subcutaneous tissue of the area. They always have to be protected and the wart formation guarded against (Figs 4 and 9). If hair is transplanted, it will continue to grow, except that it may be worn off.

Skin grafts transplanted to normal mucous membrane surfaces, such as the mouth, larynx, and eye socket, show no evidence of a change to a mucous membrane. The skin simply persists as such and even raises hair in these areas if there are any functioning follicles in the graft.

The results of grafting vary in different regions and with the type of lesion. A graft put on a soft base with a good blood supply can be expected to be more certain than if put over the shin or ankle where there is little deep pad

Fig 2 Difficult contracture of mouth and neck, repaired with three thick split grafts from clavicle to level of nose. Contour has remained satisfactory after 13 year growth period.

to help absorb shocks and trauma. Likewise, an old x-ray burn or leg ulcer with deep and surrounding fibrosis and lack of resiliency of the tissues cannot afford as good a bed or area for a graft as a simple burn. Old chronic leg ulcers with deep scarring and edema tend to recur, so that improvement of local circulation is necessary if the repair is to prove efficient, the graft itself, of course, may assist in this

scribed What would be a good functional result on a leg or axilla would be a very poor one on the face, because of roughness and pigmentation However, the same general rule applies for a late, desirable cosmetic result as for function if the graft has been satisfactory soon after operation, it will probably persist as such The unevenness and wrinkling can be minimized by careful dissection of the base and by using full thickness rather than split grafts However, chances of too much pigmentation persist without relief at the present time, and the patients may have to rely on the application of cosmetics (Figs 1, 2, 3)

By studying these patients several years after operation, the fundamentals of treat-

Fig. 4. Replacement in operation with full thickness graft of entire palmar surface of hand and fingers. The graft has definitely enlarged and is satisfactory to the boy in every way after 3 years of growth, following first recording.

A frequent cause of loss of grafts applied for long-standing fibrosed ulcers is failure to remove the scar down to soft tissue. One should avoid denuding bone or tendons in the process, however.

Although grafts and flaps are not being compared, a successful graft may be more apt to continue satisfactorily throughout a growing period than a pedicle flap because flaps have a tendency to hump up and become heavy from fat rather than to spread out.

Cosmetic results with free skin grafts may not be as good as the functional results de-

Fig. 5. One of the most difficult types with heavy distorting scar enclosing entire nose and ear. Required split

grafts but complete function of the skin grafts persists after 4 year period of growth.

Fig 9 Restoration in 1 split graft preceded by bone correction by Dr Crego. Function satisfactory with graft on sole of foot after 9 years of growth. Free grafts can work on the foot only if sufficient deep pad has been left, otherwise, a thick pedicle flap is used.

Any method that leaves behind enough skin for healing, splits through the skin, and for this reason the term "*thick split graft*" has been used. Many other names have been suggested but the term "*thick split*" seems most descriptive. The usual thickness is from one-half to three-fourths of the skin and the thickness can be graduated in cutting with some practice. The thickness of the graft varies in relation to the full thickness of the skin which, itself, varies greatly according to age, nutrition, race, and its position in the body. The actual measurement of the thickness of the graft has to be in relation to these variables. The main essentials are a long, sharp knife and some means of creating a diaphragm of the skin on which to cut.

Saving a good donor site on badly burned patients is important for obtaining smooth full thickness grafts when the final operations are to be done about the face and neck. Usually an entire thigh or the lower abdomen can be left for this work, but it is frequently found that pinch grafts have been removed right out of the center of these areas.

Fig 10 Generalized skin shortening of 26 years' duration that prevented sitting down normally. Relieved with thick split skin grafts and shown after 15 years' duration of function.

With these criteria fulfilled, *huge areas may be grafted*. Up to 600 square inches have been done in one patient and 100 to 200 square inches at a time are possible. To do this, huge grafts are necessary and they have been taken as large as 36 inches by 4 inches. To try to repair large areas with small chips of grafts is uncertain and nerve-racking. Even at best, long operative times are necessary and the condition of the patient must be watched closely.

However, when large areas are grafted at one sitting, the *total* amount of work which must be carried out is greatly lessened (Figs 7 and 8).

It seems definite that large surface repairs can be done successfully with free grafts without resorting to the cumbersome use of flaps in most instances. Growth (or stretching) of the grafts occurs so that, even after the patient has passed through long periods of growth, the restorations are found to be satisfactory.

Fig 8 Complete flexion from split graft operations. \ foot drop even though nerve as exposed in dissection.

Patient came in for amputation. Recorded second time after 9 year growth period.

ment for early lesions have been made more clear and may be briefly outlined.

Repairs of large surface defects if possible should be made early before debilitation, scarring and contracture have taken place. Most burns can be made clean enough to graft in 3 or 4 weeks, but, if good care is not given the areas, infection pain and debilitation develop and late deaths may occur (Fig 7)

Homografts may be used for temporary relief during waiting periods, but these grafts never persist in spite of attention to blood grouping down into the 'm and n subgroups. What does happen is usually a 'take' of the grafts with a period of respite from the painful dressings for several days or weeks. With this there is a general improvement, a clearing up of infection and, because of these things, a stimulation to spontaneous epithelization. Therefore actual healing may occur even though the homografts are completely absorbed and this process may be so marked that some observers may think the homografts themselves have persisted (Fig 6)

Pinch grafts or small deep grafts are used occasionally in areas that are covered by

clothes and have the advantage of not requiring a major operation. However they are unsightly in any area and may be replaced later with larger grafts if desirable

When large areas are to be dealt with consistently it is advisable to develop a *simple direct method of cleaning wounds obtaining large sheets of grafts* of suitable thickness and applying them accurately to insure growth. *The donor site* of these grafts is most important and when large areas are denuded, it is necessary to split through the skin to leave some deep gland elements to dedifferentiate into squamous epithelium so that a new surface may form. With careful dressing of the donor site surface healing will be satisfactory in 12 days. As many as four crops have been taken from the same area and one crop taken 19 days after the previous one. If the reverse is true, that is if the skin is cut through or the donor site becomes infected healing will be delayed for weeks and no subsequent crops can be taken. This is somewhat comparable to the loss of epithelial healing that occurs under an infected tannic acid or silver nitrate crust (Fig 8)

OBSERVATIONS

There were no deaths in either series. One dog in the second series at the end of the second month developed a sudden increase in weight and what was thought to be ascites. The icteric index suddenly rose, although the animal's clinical condition remained excellent. The fluid wave in the abdomen disappeared just as suddenly and the jaundice receded. At the end of the period of observation the dog was sacrificed, the stomach was hugely dilated and contained several large pieces of bone which apparently had obstructed the pylorus and angulated the common duct.

Red cells and hemoglobin All of the animals developed a drop in the red cell count and hemoglobin concentration. The dogs which had had the gall bladder out in addition to the obstruction showed a marked initial decrease, but after the first week the average variations were insignificant. The series of dogs with just the obstruction showed a slower but similar decline with the leveling of the curve occurring only after 3 weeks. The dogs in which the gall bladder had been removed did not show as great a total drop as those dogs with the obstruction alone.

Each animal over a period of 3 months lost approximately 400 cubic centimeters of blood. This loss in repeated amounts of 30 cubic centimeters does not seem great enough to explain the developing anemia. Snell, Greene, and Rowntree (40), after ligating the common duct and removing the gall bladder, noted a steady fall in the number of red cells with a slight reduction in hemoglobin. They attributed this result to repeated bleeding. Mann and Bollman refer to the anemia that is associated with liver injury. This may have been a factor in the present series in addition to the chronic blood loss.

Blood clotting The coagulation time according to the method of Lee and White (25) was done each time blood was taken. The average coagulation time curve in the series with the gall bladder present showed a slight decrease, but the difference was not great. In general, the coagulation time showed no significant variation. In support of this observation none of the dogs showed any tendency to bleed. Lee and Vincent (24) have stressed the dura-

tion of jaundice as a factor in causing an increase in coagulation time. Since the icterus in these animals lasted only 2 to 3 weeks, a change was not to be expected.

Icteric index In the first series with the gall bladder in place the maximum rise in the jaundice did not occur until the seventh day. When the gall bladder was removed, in addition to the obstruction to the common duct the jaundice was highest in all but 1 of the animals from the third to the seventh day after operation. Thereafter, in both series the icteric index gradually diminished and returned to normal during the period of observation. This acute rise when the gall bladder was absent has been demonstrated previously, it was to be expected, since the gall bladder was not present to store the secreted bile. The speed by which obstruction to the common duct becomes apparent has been demonstrated by Snell and his co-workers (41). They found a direct van den Bergh reaction $1\frac{1}{2}$ hours after ligation of the common duct and removal of the gall bladder while the serum bilirubin increased to 2.2 milligrams per 100 cubic centimeters in 4 hours.

Urea nitrogen The blood urea nitrogen in both series showed an initial decrease, then a rise between the fourteenth and twenty-first days, and decreased from then to the end of the period of observation. These variations were more marked in the series with the obstruction present and the gall bladder removed. It is difficult to explain why the presence or absence of the gall bladder should make this difference. Since the values for the blood urea nitrogen varied conversely with the icteric index, some degree of temporary hepatic insufficiency is suggested as the cause. If this explanation is valid, the larger variations in the blood urea nitrogen in those dogs which had had the gall bladder removed in addition to the obstruction postulate a greater degree of early hepatic damage in that series. Previous observers have all demonstrated a decrease in the blood urea in the presence of jaundice or after hepatectomy (Yanagi and Bollman, Mann, and Magath).

At the end of the experiments the curves in both series approximated each other. It must be pointed out that all the values are within

THE EFFECT OF PARTIAL OBSTRUCTION OF THE COMMON BILE DUCT

NORMAN W THIESSEN, M.D. and RAMON F HANZAL, Ph.D. Cleveland, Ohio

PARTIAL or recurring obstruction to the common bile duct in man causes many distressing symptoms. In the absence of stone stricture or cancer these symptoms have been attributed variously to dysfunction of the gall bladder tonic or structural disturbances of the sphincter of Oddi, and inflammation of the pancreas. The differential diagnosis of these conditions, when jaundice is not present is difficult. Any diagnostic help therefore would be a distinct assistance. An attempt was made experimentally to produce a similar condition in the dog by causing a partial obstruction to the common bile duct and to observe the effects.

The first clinical report of "gall-bladder colic" without stone or infection was made by Krukenberg in 1903. Aschoff and Baczmeister (3) in 1909 described what they called the stasis gall bladder distinguishing the hypertrophic and atrophic types, depending on the condition of the muscle layer of the gall bladder. In 1920 Schmieden (38) correlated the pathological with the clinical findings and stressed mechanical hindrances to the flow of bile as the cause of the symptoms. Berg in 1922 found a hypertrophy of the sphincter of Oddi and suggested a functional disorder of this muscle as the cause for biliary stasis. This observation has been confirmed since then by Westphal (48). Nuboor Newman Giordano and Mann (15). This theory already had been suggested on physiological grounds by Oddi and by Meltzer. Westphal (49) then classified these states as atonic and hyperkinetic with a further differentiation of the hyperkinetic type into hypermotile and hyper-tonic states. More recently several observers have demonstrated a physiological obstruction to the lower end of the common bile duct in man (McGowan, Butsch, and Walters (28).

Ivy (19) Best and Hicken) Similar obstruction caused by pancreatitis has been shown to occur by Thieszen and Walters (43)

METHOD

In the first series of 5 dogs, under barbital anesthesia and with an intratracheal tube in place, the common bile duct was exposed. It was dissected completely free from surrounding tissue just proximal to its entrance into the duodenal wall. This portion was carefully selected so as to be distal to the junction of the bile duct from the right lobe of the liver and the common duct. At this point a silver clip was placed around the duct so as to include the duct and a stylet measuring 18 millimeters in diameter. The ends of the clip were pressed firmly together and the stylet was removed, thus allowing the clip to remain in place. The abdominal incision was closed in the usual manner.

In the second series of 5 dogs the same procedure was carried out but in addition a cholecystectomy was performed.

After operation the dogs were rarely sick and food was taken on the first day. The diet was a standard one of cereal and meat scraps.

Samples of blood were taken in the fasting state before the operation on the first, third, and seventh days after operation and weekly thereafter for a total of 13 determinations on each dog over a period of 6 weeks. The coagulation time according to the method of Lee and White (25) was done at the time the blood was drawn. The number of red cells and the concentration of hemoglobin was determined. The remaining blood was then analyzed for cholesterol, cholesterol esters, total calcium, urea nitrogen, fibrinogen and serum bilirubin stated as icteric index. The weight of the dog was noted at the time of each blood sampling. All stools were tested for the presence of bile by the Schmidt test to rule out the possibility of complete obstruction occurring.

Since the values for the blood urea nitrogen varied conversely with the icteric index, some degree of temporary hepatic insufficiency is suggested as the cause. If this explanation is valid, the larger variations in the blood urea nitrogen in those dogs which had had the gall bladder removed in addition to the obstruction postulate a greater degree of early hepatic damage in that series. Previous observers have all demonstrated a decrease in the blood urea in the presence of jaundice or after hepatectomy (Yanagi and Bollman, Mann, and Magath).

At the end of the experiments the curves in both series approximated each other. It must be pointed out that all the values are within

Fig. 1. Curves of average values. — Series I, partial obstruction of common bile duct. - - - Series II, partial obstruction of common bile duct with cholecystectomy.

normal limits, despite the observed rise and fall.

Calcium. The total blood serum calcium in the first series with only the obstruction showed a rise and then a fall. In the second series there occurred a slight steady rise, the significance of which is questionable.

The literature has many conflicting reports on both the quality and quantity of the blood calcium in jaundice (Ivy 20). The presence of icterus has some effect on the metabolism of calcium as shown by the bony changes occurring in prolonged jaundice (Buchbinder and Kern 9) by the greater tolerance of the jaundiced dog to intravenous calcium (Walters and Bowler) and by the decreased effectiveness of parathyroid extract in parathyroidectomized dogs with jaundice (Buchbinder and Kern 10).

Fig. 2. The lower end of the common bile duct in dogs, showing the strictures produced. On the left the silver clip has ulcerated through only partially.

Fibrin. The fibrinogen content of the blood increased in both series. Snell, Greene and Rowntree (41) observed a sharp postoperative rise in blood fibrin after ligation of the common duct followed by a decrease to the upper limits of normal. The changes observed are in accord with the belief that damage to the liver causes a rise in blood fibrinogen and fibrin.

Cholesterol and cholesterol esters. The values for total blood cholesterol varied similarly in both series. There was a rise to a peak at the end of 7 days, a sharp fall at 14 days, a secondary rise between the thirty-fifth and forty-second day, with a final drop to the pre-operative level (Fig. 1).

The cholesterol esters, on the other hand, reacted conversely in the two series. In the series in which the obstruction was present alone the percentage of esters rose as the total cholesterol fell and fell when the total cholesterol rose. When the gall bladder was removed in addition to the presence of the partial obstruction, the changes in cholesterol esters paralleled the changes in total cholesterol (Fig. 1).

The significance of these changes is hard to evaluate. It is generally conceded that a rise in free cholesterol with a fall in the esters means liver damage (11, 14, 17, 23, 33, 37). In both the series of dogs one may postulate approximately an equal amount of ultimate liver damage. The difference, therefore, should be due to the presence of the gall bladder in the

first series Sweet reported that after cholecystectomy the blood cholesterol rose and did not return to normal for 40 days. Previous experiments by many workers (1, 2, 4, 11, 12, 16, 18, 23, 31, 32, 33, 44) on the action of the gall bladder on cholesterol metabolism are contradictory, the best data appear to show that the normal gall-bladder mucosa may absorb small amounts of cholesterol, while the inflamed mucosa may add cholesterol to the gall-bladder bile by desquamation (Ivy, 19,

Tornoumi). The changes described would signify then, that the rise in total cholesterol is in response to liver damage, while the change in the esters is caused by an absorption of cholesterol from the bile with the amount of the esters in the blood remaining the same. This resulted in a relative drop in the cholesterol-cholesterol ester ratio. When the total cholesterol value dropped, the percentage of esters remained more or less the same, and the relative increase of esters became apparent.

TABLE II—BLOOD CHANGES FOLLOWING PARTIAL OBSTRUCTION TO COMMON BILE DUCT AFTER CHOLLECYSTECTOMY

It has been shown that during fat absorption the proportion of cholesterol esters is high (Bloor and Knudson 7, 21 and Currie). Pathologically cholesterol deposits may be seen in any tissue in which cells are under going destruction and where absorption is poor (Wells). If these observations are accepted it is quite possible that the rise in the level of the esters is an absolute one caused by degeneration of the liver secondary to obstruction.

The secondary rise in total cholesterol coming between the fifth and sixth weeks may have been due to the liver damage becoming more apparent before the healing process began.

It was suggested that the variations in cholesterol and its esters may have been due to the nutritional state of the animals. These variations of the serum lipoids with the state of nutrition have been studied (Man and Glöden, and Wendt). In general, during starvation an initial hypocholesterolemia occurred after which the cholesterol values varied with the state of nutrition. In both series of observations reported here the initial drop in total cholesterol did not occur although there was a definite loss in weight. The total cholesterol rose until the seventh day. Thereafter in the dogs with the partial obstruction present and the gall bladder removed the two curves varied directly (Fig. 1). At the end of the period of observation, however when the cholesterol returned to normal, the weight had fallen appreciably. In the series of dogs with only the obstruction, after the initial rise in cholesterol, the two curves varied inversely, similar to the cholesterol-cholesterol ester curves in the same dogs. From these results it cannot be said that the changes in the blood cholesterol were caused by the variation in the state of nutrition.

It is more probable that the changes in the total cholesterol are the result of the liver damage.

At the end of the experiment the presence of partial obstruction was proved at autopsy. All the dogs showed strictures at the point where the clip had been placed (Fig. 2). The clips had ulcerated through and in 4 dogs it was found lying free in the upper common

duct. The bile back of the structure contained small sandy particles and was turbid. The liver was cirrhotic in all the dogs. The pancreas was normal. The duodenum and stomach showed gross inflammation only in 2 dogs.

SUMMARY

A study of the comparative effects of partial obstruction to the common bile duct with and without cholecystectomy was made (Tables I and II). It was hoped that some help might be obtained in explaining symptoms arising from partial or recurring common duct obstruction in man. The observations in the main agree with those noted after ligation of the common duct differing only in degree. A peculiar variation in the cholesterol-cholesterol ester ratio has been shown to occur. In the presence of obstruction and an intact gall bladder the cholesterol esters increased when the total cholesterol decreased, and decreased when the total cholesterol increased. In the presence of obstruction and with the gall bladder removed, the cholesterol esters varied directly with the total cholesterol. The evidence favors the view that these variations result from damage to the liver with the gall bladder playing a secondary rôle rather than from changes in the state of nutrition.

tetanus toxins when injected subcutaneously into guinea pigs and white mice, do not give rise to tetanus but lie dormant as inert bodies at the point of injection, awaiting either destruction by phagocytes or an awakening into activity and toxin production by tissue destruction or secondary infection. It would, therefore, seem that the symptoms of tetanus which Babes observed in his animals were due to the amount of toxin that was injected with the bacilli in the cultures, and the important factor of toxin content was not controlled. It is quite plausible that the animals receiving a sublethal amount of tetanus toxin survived, while those receiving a fatal dose died. That he was able to save 1 of 2 animals inoculated with a culture of *Clostridium tetani* following the injection of the blood of a rat which had survived inoculations of *Clostridium tetani* and phenol may be explained on the basis that either the toxin injected was of a sublethal quantity, or that there was sufficient antitoxin in the blood of the rat to render the recipient animals passively immune. Of course, both factors may have played a part. In either event, it would be impossible to state that the phenol played any significant rôle.

McClintock and Hutchings performed some experiments similar to those of Babes. In their first experiment they used 5 pigs and gave each subcutaneously ten times the minimal fatal dose of U. S. standard tetanus toxin. As soon as symptoms developed the pigs were given 0.5 cubic centimeter of a 20 per cent phenol solution subcutaneously every 2 hours during the day. All of the pigs died and no effect was observed. They repeated this experiment and gave the phenol every 2 hours day and night. In this experiment 2 of the pigs recovered. They again repeated the experiment, the phenol injections being started immediately after the injection of the toxin. In this case all of the pigs died. Similar results were obtained in experiments on sheep. It did appear to them that the sheep were less spastic when treated with phenol than with antitoxin.

Camus, working with dogs, found phenol of no value in treating tetanus, regardless of the amounts used, or at what stage of the disease

the phenol was administered. He used tetanus toxin and a 30 per cent aqueous solution of phenol subcutaneously in varying amounts. The largest amount of phenol used was 20 cubic centimeters daily. The controls and the phenol injected dogs died in about the same time, i. e., 5 to 6 days. The dogs injected with phenol 24 hours after the administration of the toxin died at the same time as did the dogs which received the injections at the time the signs of generalized tetanus developed. Flores obtained similar results. He used 11 guinea pigs, giving each one a fatal dose of toxin intramuscularly, and at the first signs of tetanus administered a total of 3 cubic centimeters of a 10 per cent aqueous solution of phenol daily in fractional doses. Four of the guinea pigs died on the second day and the remainder on the third day. The 17 control animals died in 2 to 4 days, 14 of them on the third day.

It would seem from the 3 latter reports that the phenol treatment, as recommended by Baccelli, is of no benefit. However, there are many clinical reports of the cures of cases of tetanus with phenol injections, including a number of cases which had trismus and opisthotonos with generalized spasms. Most of the reports are based upon only 1 or 2 cases. Very few fatal cases have been reported in which this therapy was used. Baccelli, in 1911 (4), collected 190 cases from the literature from 1888 to 1911. These cases were from about one hundred different physicians. Baccelli divided the cases into groups. He classed 94 as severe, of which he stated 92 were cured, the mortality being decreased according to his calculation from 100 per cent to 2.12 per cent. He discarded from this group all cases which did not receive at least 1 gram of phenol per day. In the group that he classified as being very severe there were 38 cases, 11 of which, he stated, did not receive sufficient phenol. From the 27 cases that he thought did get sufficient phenol 22 were cured, a mortality, according to Baccelli, of 18.5 per cent. He stated that the average maximum dose was 1.5 grams of phenol per day, but often more was given. Single doses ranged from 0.1 to 0.15 gram. It was possible, however, to increase the dose in a 9 year old boy to 0.75

THE EFFICACY OF PHENOL AND TETANUS ANTITOXIN IN THE TREATMENT OF EXPERIMENTAL TETANUS

WESLEY D THOMPSON J M.D. and LEON FRIEDMAN M.D. Phil delphus, Pennsylvania

THE use of phenol in the treatment of tetanus antedates the isolation and culture of the *Clostridium tetani* by Kitasato in 1889 (15) Guakdi, a student of Baccelli, in 1888 reported before the First Italian Congress of Internal Medicine the excellent results obtained by him and Baccelli in the treatment of several hundred cases of neuralgia, sciatica, and other conditions by the injection of aqueous solutions of phenol. Finding the chemical to be a powerful analgesic and sedative, they were tempted to try it on a severe case of tetanus. The patient recovered. Baccelli became a staunch advocate of this type of treatment which has become identified with him to the extent that it commonly bears his name.

In his paper in 1911 Baccelli referred to the work of Kitasato (16) in 1891 and that of Babes (2) in 1892 as lending experimental support to the use of phenol in the treatment of tetanus. Kitasato discovered that phenol, when mixed with a filtrate from a culture of *Clostridium tetani*, *in vitro* would detoxify the toxin. He found that when equal amounts of a 3.0 per cent phenol solution and filtrate were combined and the mixture allowed to stand for one hour 0.1 cubic centimeter of this solution would not cause tetanus when injected into mice. It required only .00001 cubic centimeter of the filtrate itself to kill a mouse in 5 to 6 days. Baccelli failed to mention in his paper that Kitasato also found other chemicals to be of benefit in even lower concentration. For example, hydrochloric acid was effectual in 0.5 per cent solution, cresol in 1.0 per cent solution calcium hydroxide in 0.1 per cent solution and sodium hydroxide in 0.3 per cent solution.

In referring to the work of Babes, Baccelli stated that this investigator found that he

could immunize animals to tetanus with the blood or serum of several species of animals which had been previously 'immunized' by injections of phenol. This "experiment" consisted in taking blood from the heart of a rat which had survived *Clostridium tetani* and phenol injections, and injecting this into two guinea pigs. Both animals were then injected with a culture of the *Clostridium tetani*. One survived. He obtained the same results using rabbits.

In 1898 Babes (3) summarized his experiments, stating that he had cured dogs which had been inoculated with a virulent culture of *Clostridium tetani* by injecting them five times daily with 25 cubic centimeters of a 0.5 per cent solution of phenol, even when the treatment was delayed until first symptoms appeared. All the control animals died but all of the treated dogs recovered in about 9 days. Relaxation of muscle spasm appeared first at the point of the phenol injections. Pigeons were also used. 6 were inoculated with a culture of *Clostridium tetani*, and as soon as the first signs of the infection appeared, 3 were injected 8 times daily with 1 to 2 cubic centimeters of a 1.0 per cent solution of phenol. The treated animals survived while the 3 controls died. Similar results were obtained in rabbits but rats were rarely saved. The results in these experiments were much more constant than in similar experiments reported in 1892 in which he used a 1:1000 solution of phenol. In closing he said "The general result of this treatment is very remarkable and hardly less manifest than the action of antitetanic serum. The animals cured were not however absolutely immune to new tetanus inoculations but succumbed after repeated injections of toxin."

It does not appear that any definite conclusions can be drawn from these experiments for Francis and Vaillard and Rouget found that tetanus spores in pure culture and free from

† unit intracutaneous 1000 M.C.D.

gram every 12 hours, for 12 days. Other patients were given as much as 3.0 grams per day for 14 days without apparent harm. He himself used a 2.0 to 3.0 per cent aqueous solution and gave not more than 0.3 to 0.5 gram the first day but if the urine remained normal, he quickly increased the dose from 1.0 to 1.5 grams per day in divided doses. Woods used a 10 per cent solution and Maragliano used a 5 per cent solution in sterile oil to avoid the local effects of phenol especially in new born babies. In the very severe cases, Baccelli advised the immediate injection of 1 gram the first day.

As a result of Baccelli's paper there was from 1911 to 1914 a gradual increase in the publications of isolated cases of tetanus cured by phenol. However from 1914 on the reported cases became rarer. Bruce in 1915 (7)

and 1916 (8) stated that magnesium sulphate and phenol had been used in the cases of tetanus in the home hospitals of England but had been found to be of no value. In the first report 7 patients died of those receiving subcutaneous doses of less than 16.2 grams of phenol per day and 5 recovered, while of those receiving from 16.2 to 80.0 grams per day 7 died and 6 recovered. In the second report about the same ratio prevailed. All of these patients also received tetanus antitoxin. Leishman and Smallman, in their analysis of the cases of tetanus in the British Expeditionary Forces in France, reported no favorable results from the use of phenol. However they reported neither the amount of phenol used nor the method of administration. Stricker writing on tetanus in Germany during the war made no mention of the phenol

Fig 1 Dog 418, cord Received 100 DLD of tetanus toxin (pulverized) intravenously Sacrificed at 25 hours when near death Anterior horn cells show acute cell disease with loss of Nissl substance and pale staining of cell prolongations far from the cell The nuclear membrane is lost a, left, $\times 500$, cresyl violet stain b, $\times 400$, cresyl violet stain

Three American authors reported favorable results following phenol and antitoxin treatment. Bryan reported 6 cases with 6 recoveries. He used the phenol intravenously in a 1.0 per cent solution giving from 30 to 40 cubic centimeters every 8 hours. In addition, these patients received from 65,000 to 105,000 units of tetanus antitoxin. Bates reported 4 recoveries out of 5 cases following Baccelli's technique while Miller reported 1 successful case following the method used by Suvansa. Both of these authors also gave large doses of tetanus antitoxin in addition to the phenol. Prior to these reports, Beall in 1924 reported 8 successfully treated cases using 1 to 2 grains of phenol intramuscularly every 4 hours usually in a 1.50 per cent aqueous solution. In addition his patients received 30,000 units

of tetanus antitoxin on the first day. They all had trismus and convulsions. The incubation periods were reported in 5 cases and ranged from 2 to 12 days.

In many of these cases the tetanus antitoxin alone might have effected a cure regardless of the amount of phenol given yet it is not possible to state that the phenol did not supplement the antitoxin.

What can we conclude from these reported clinical successes? A patient will not succumb to tetanus unless he gets a full lethal dose of the toxin but just what a lethal dose is for man we do not know. There is no doubt that it will vary with the individual due to difference in host resistance. Furthermore, there is no test by which we can tell just how much toxin the patient has fixed or will absorb. Following the clinical course of the disease may help but little because we never know the exact incubation period, the number or virulence of the *Clostridium tetani* or their rate of toxin production. If we knew these facts we could then better prognosticate in the individual case. Even though it is theoretically possible for a patient to absorb and fix seven-eighths of a fatal dose of toxin and not die it is hardly possible to believe that all of the cases reported as having been cured by phenol alone would fall into this group. Because of the great expense involved in the treatment of tetanus with adequate amounts of tetanus antitoxin we felt that it would be of importance to carry out some controlled experiments in an attempt to determine the value of phenol in the treatment of experimental tetanus alone and in combination with antitoxin.

PART I

Method. We first investigated the method advocated by Suvansa (23). We assumed that he would use his maximum dose of 40 cubic centimeters in treating a young well developed man of 150 pounds with a severe case of tetanus. From this we obtained our intrathecal dose of 0.57 cubic centimeter per kilogram of body weight of a 1.400 phenol solution in normal saline. We desired to use a dose of tetanus toxin that we knew would kill the dog, regardless of the amount of tetanus

Fig 4 Dog 594, cord Received 100 D L D of tetanus toxin (pulverized) intravenously and 6 hours later 0.57 cubic centimeter phenol (1.400) per kilogram of body weight intrathecally Dog died in 20½ hours from tetanus Acute cell disease in anterior horn cell with loss of Nissl

substance, pyknosis of nucleus and swelling of nucleolus a, $\times 840$ cresyl violet stain b, Thrombosis and liquefaction of gray matter around it $\times 105$ c, Incrustation of pericellular glia network around degenerated anterior horn cells $\times 840$

antitoxin administered Abel and Chalian had found that if 100 D L D¹ of tetanus toxin were injected intravenously and 6 hours allowed to elapse, no amount of tetanus antitoxin could save the animal We, therefore, decided to use this amount, since we felt that by so doing we could tell whether phenol was of any benefit in extreme tetanus, either alone or in combination with tetanus antitoxin

Experimental data Healthy, young, adult dogs were used for each group of experiments A complete autopsy was performed on each animal that died or was sacrificed

Experiment 1 (1) The length of time required for dogs to die after the intravenous administration of 100 D L D of tetanus toxin was determined The symptomatology was carefully observed in the 6 dogs as tetanus developed (2) The effects of intrathecally

administered phenol (1.400) given in the dosage of 0.57 cubic centimeter per kilogram of body weight were studied in 3 dogs to which no toxin was given (3) Three dogs were given intravenously 100 D L D of tetanus toxin, and at the end of 6 hours were given intrathecal injections of phenol (1.400) in the same dosage as stated The progress of the disease and the length of time that the dogs survived were noted (4) Three dogs were prepared as in the third group, but instead of intrathecal phenol they were given at the end of 6 hours 200 times the neutralizing dose² of tetanus antitoxin intravenously and the subsequent course observed (5) In 1 dog we combined the above 2 forms of therapy so that at the end of 6 hours the dog, which had received 100 D L D of tetanus toxin, was given both intrathecal phenol as in No. 3, and 200 times the neutralizing dose of tetanus anti-

¹From Abel and Chalian "We have found in the course of very numerous experiments extending over a period of 5 years that injection of 450 guinea pig L. D. 50's per kilogram invariably induces fatal tetanus in dogs of medium weight and age, and have therefore arbitrarily chosen this figure as our lethal dose for dogs This dose kills dogs at random in from five to nine days

²According to the United States Government standard one unit of tetanus antitoxin will neutralize 1000 minimal lethal doses of tetanus toxin Therefore 200 times the neutralizing dose would be 200 times the amount of tetanus antitoxin which would be necessary to neutralize the total injection of the tetanus toxin

tetoxin as in No. 4. All of our intrathecal administrations were made through the lumbar route with a regular spinal puncture needle while the dogs were under ether anesthesia.

This series of experiments (Table I) revealed that dogs given 100 D.L.D. of tetanus toxin invariably died in 25 to 26 hours when the freshly prepared dry toxin was used, and in 42 to 44 hours when the toxin in solutions (of equal strength when prepared sometime prior to the experiment) was used. Histological study of the central nervous system revealed the toxic myelopathy so often described in tetanus (Fig. 1) while that of the kidneys revealed a simple nephrosis with passive congestion, the livers an acute passive congestion with parenchymatous degeneration most marked in the central zones. Dogs given phenol alone intrathecally showed no clinical effects, but the histological study of the cord and brain after the phenol was injected revealed a thickening of the meninges (Fig. 2) the kidney a mild simple nephrosis, and the liver a mild cloudy swelling. The dogs given tetanus toxin intravenously plus phenol intrathecally died about 5 hours sooner than the controls. Histological study of the central nervous system here revealed a toxic myelopathy greater than that observed with tetanus toxin (Figs. 3 and 4). However the kidney and liver showed much the same pathological picture as that found with toxin alone. The dogs which were given 100 D.L.D. of tetanus toxin and then after 6 hours treated with 200 neutralizing doses of tetanus antitoxin did not die of tetanus as predicted by Abel and Chellan. One dog survived and showed no ill effect whatsoever from the tetanus toxin and was in excellent condition when returned to stock 1 month later. Another dog developed local tetanus in the injected hind limb and was sacrificed at the end of 11 days. It at no time showed any signs of generalized tetanus. The remainder of the dogs died from intercurrent infection yet all but one lived sufficiently long after tetanus was expected to develop to preclude its subsequent development.¹ In the last

phase only 1 dog was given similar amounts of tetanus toxin and then treated at the end of 6 hours with both phenol and tetanus antitoxin. As would be expected from the above it also showed no signs of tetanus, but died from an intercurrent infection yet sufficiently long after the experiment was started similarly to preclude any development of tetanus. None of these dogs showed any of the neurological involvement seen in tetanus.

These experiments demonstrated that dogs given overwhelming doses of tetanus toxin known to kill healthy dogs in from 24 to 26 hours, are not helped. If anything their death is hastened by additional central nervous system damage or lowered resistance to distemper when given phenol intrathecally 6 hours after the tetanus toxin is given intravenously while the use of tetanus antitoxin alone in sufficient amounts can save the dogs when given 6 hours after the toxin.

Experiment 2 In this group of dogs, we administered the same dosage of tetanus toxin and phenol as in the first experiment, but instead of waiting 6 hours to inject the phenol we administered it as soon as possible after the toxin injection. The results both as to the length of time before death from tetanus and to the histological findings, were similar to the findings in the first experiment.

PART II

We felt that the above experiments revealed that phenol administered intrathecally in the amounts used was of no value in neutralizing or detoxifying large doses of tetanus toxin given intravenously to dogs, regardless of the time of administration. We, therefore began our investigation of the intravenous use of phenol as advocated by Corrigan and Bryan.

Method These authors have found clinically that fairly large amounts of a 10 per cent phenol solution were compatible with life. We, therefore adopted this percentage. Our solution was made by adding the required amount of liquid phenol of a known concentration to normal saline just prior to its use

¹Under similar circumstances, have found that if the dogs did not show signs of tetanus within 48 hours, they would not subsequently develop them. A. Chamberlain, Glasgow, told us that he had 10 dogs as saved from tetanus, although they may have succumbed at their time of birth from another infection. The first signs of distemper noted were paralytic dis-

charges from the nose and eyes. These were followed by cough, loss of appetite and general debility. Of the dogs that died or were sacrificed, varying degrees of pulmonary disease were found at postmortem. These changes ranged from simple bronchitis with pulmonary congestion to acute or lobular pneumonia with thoracic formation.

Fig. 5. Dog 036, cord. Received unpreserved tetanus antitoxin intrathecally and was sacrificed 17 hours. Mild lymphocytic infiltration in the arachnoid around an anterior nerve root. $\times 295$, cresyl violet stain.

normal position in which they were placed. Within 6 to 8 hours marked conjunctival edema was noted which in some cases resulted in a complete obliteration of the pupil. In the animals which received lethal doses of phenol these signs were progressive until death, while in the others the signs were less severe and entirely disappeared within 24 hours. Histological examination of the sections taken from the kidneys and livers revealed a simple nephrosis and mild cloudy swelling. These findings were, of course, most marked in the dogs receiving the larger amounts of phenol. We concluded that in dogs the lethal dose of 1.0 per cent intravenous phenol was between 0.3 and 0.35 gram per kilogram of body weight, and that the damage to the kidney and liver was in direct proportion to the amount of phenol given.

Experiment 2. The purpose of these experiments was to determine whether or not the intravenous injection of phenol in one hind limb would prevent or prolong the appearance of tetanus when 100 D.L.D. of tetanus toxin

was simultaneously injected into the vein of the other hind limb. Because of the known damaging effects of both tetanus toxin and phenol we decided to use a dosage of phenol which in itself had minimal effects. Bio-assays were run on the bloods from all the dogs. The blood samples were taken in each instance at the conclusion of the injections. There were 3 dogs in this group (Table II) one control and two dogs receiving both phenol (0.107 and 0.143 gram per kilogram of body weight respectively) and tetanus toxin. All three of these animals died between 26 and 30 hours and all of the bio-assay determinations were found to be equal. Histological changes in the kidneys and liver were about the same as in the preceding experiment. We therefore concluded that intravenous 1.0 per cent phenol in the dosage mentioned, given simultaneously with 100 D.L.D. of tetanus toxin through opposite veins in the same fluid volume did not alter the progress of tetanus and the bio-assays did not reveal any detoxifying effect of the phenol.

Experiment 3. Although the above experiments were negative we decided to repeat them but using only 10 D.L.D. of tetanus toxin. In this series we had 2 controls and 6 experimental dogs (Table II) which received, respectively in addition to the toxin, 0.117, 0.117, 0.125, 0.222, 0.30 and 0.35 gram of phenol per kilogram of body weight. The controls died of tetanus in from 46 to 68 hours, the phenol dogs died of tetanus in from 46 to 66 hours with the exception of the last dog that received 0.35 gram of phenol per kilogram of body weight. This dog died in about 20 hours from phenol poisoning. The bio-assays in all the animals remained equal except in the 2 dogs which received larger amounts of phenol, and in these the bio-assays showed their blood to be more toxic for guinea pigs than that of the controls. It was noted in experiment 1 that in a normal dog the maximum tolerance was between 0.3 and 0.35 gram of phenol per kilogram of body weight. During this series it was found that the time of death of the last animal was approximately the same as that of the dog which received 0.35 gram of phenol

(The authors are deeply indebted to Dr. F. O. Jones of the Biological Department of the Lilly Research Laboratories for his co-operation in securing blood samples.)

TABLE III—RESULTS OF NEUTRALIZING DOSES OF TETANUS ANTITOXIN

Dog No.	Weight Kg.	Tetanus toxin 100 D.L.D. M.L.D.	Tetanus antitoxin		Death from tetanus No. hours after toxin	Remarks
			Units T.V.† hours after toxin	Neutralizing dose Unit

centrations 1000 M.L.D.

toxin, we injected a group of 4 with this amount of toxin and after 6 hours intravenously various neutralizing doses of tetanus antitoxin (Table III). It was found that the time of death of these animals was almost in direct proportion to the amount of antitoxin administered e.g. the dog which received 25 times the neutralizing dose of antitoxin died from tetanus in 38 hours, while the animal that received 150 times the neutralizing dose died in 77½ hours. Of the 2 animals which received 100 times the neutralizing dose, 1 died in about 153 hours, while the other had no evidence of tetanus and was returned to stock 1 month later in perfect condition.

These data with those in Part I experiment 1 led us to conclude that dogs given 100 D.L.D. of tetanus toxin could be saved if between 182 and 250 times the neutralizing dose was given.

Experiment 2 Since it had been found that dogs given 100 D.L.D. of tetanus toxin

had not irreversibly fixed one lethal dose of toxin within 6 hours, we decided to prolong the waiting period to 7 hours. Similarly we also increased the dosage of tetanus antitoxin from 200 times the neutralizing dose to 300 times, because our experience in the past has shown that the dosage of antitoxin must be proportionately increased with the time interval if the animal is to be saved. To 3 dogs, therefore we gave 100 D.L.D. of tetanus toxin intravenously and at 7 hours gave in a similar manner 300 times the neutralizing dose of tetanus antitoxin. The course of these animals was uneventful until the third day when all 3 developed stiffness of the back and hind limbs (ascending tetanus was not uncommon in our experience). In 2 of the animals the signs did not progress however in 1 opisthotonos with inability to stand developed on the fourth day. The signs in this last dog remained stationary after the fourth day and seemed to be improving but the animal was found dead on the morning of the sixth day. Of the 2 other dogs, 1 developed distemper

and was sacrificed on the fourteenth day because of its poor condition. The remaining dog gradually lost the spasticity and was in excellent condition when sacrificed 3 months later. Histological examinations of the kidney and liver were normal. There was, however, considerable thickening of the dura with mild infiltration of arachnoid, but the anterior horn and cortical cells appeared to be normal.

We concluded from these experiments that dogs can frequently be saved when 300 times the neutralizing dose of tetanus antitoxin is administered intravenously 7 hours after the intravenous injection of 100 D L D of tetanus toxin, although signs of tetanus may develop. We must assume that some of the toxin was so fixed within 7 hours that 300 times the neutralizing dose of antitoxin could not inactivate it. The histological study of the surviving animal which was sacrificed 3 months later revealed that most of the pathological changes induced by tetanus toxin were reversible.

SUMMARY AND CONCLUSIONS

1 Intrathecal administration of phenol to dogs given intravenously 100 D L D of a tetanus toxin known to kill healthy dogs within 25 to 26 hours, will not prevent death of the animals. If anything, their death is hastened by the additional central nervous system damage or lowered resistance to distemper which phenol apparently produces. The administration of tetanus antitoxin in sufficient amounts does save the dogs when given within 6 hours of a similar dose of toxin.

2 The lethal dose of a 10 per cent phenol solution for dogs was found to lie between 0.3 and 0.35 gram per kilogram of body weight when given intravenously. The damage to the kidneys and livers was in direct proportion to the amount of phenol given.

3 Intravenous 10 per cent phenol in the dosage used, given simultaneously with 100 D L D of tetanus toxin through opposite veins, did not alter the progress of the tetanus and the bio-assays did not reveal any detoxifying effect of the phenol.

4 Intravenous 10 per cent phenol in the dosage used, given simultaneously with 10 D L D of tetanus toxin through opposite veins, did not alter the progress of the tetanus

and bio-assays did not reveal any detoxifying effect of the phenol.

5 The common preservatives used in tetanus antitoxin are definite irritants to the central nervous system. Tetanus antitoxin containing these preservatives should not be used intrathecally in the treatment of tetanus.

6 Dogs given 100 D L D of tetanus toxin intravenously were saved when given at 6 hours between 182 and 200 times the neutralizing dose of tetanus antitoxin.

7 Dogs given 100 D L D of tetanus toxin intravenously were saved when given at 7 hours between 182 and 200 times the neutralizing dose of tetanus antitoxin, although signs of tetanus developed. It was suggested that in 7 hours a portion of the injected tetanus toxin was so irreversibly fixed that it could not be neutralized by dosage of antitoxin given.

The authors wish to express their appreciation to Dr F H L Dr Harold M Dixon for their help in the study of biological specimens and to Dr I S Ravdin and Lockwood for their encouragement and counsel.

toxin we injected a group of 4 with this amount of toxin and after 6 hours intravenously various neutralizing doses of tetanus antitoxin (Table III). It was found that the time of death of these animals was in direct proportion to the amount of antitoxin administered e.g. the dog which received 25 times the neutralizing dose of antitoxin died from tetanus in 38 hours, while the animal that received 150 times the neutralizing dose died in 77 hours. Of the 2 animals which received 182 times the first time the neutralizing dose, 1 in about 153 hours, while the other had no evidence of tetanus and was returned to stock 1 month later in perfect condition.

These data with those in Part I of Experiment 1 led us to conclude that dogs given 100 D.L.D. of tetanus toxin could be saved if between 182 and 200 times the neutralizing dose was given at once.

Experiment 2. Since it had been found that dogs given 100 D.L.D. of tetanus toxin intra-

venously had not irreversibly fixed one lethal dose of toxin within 6 hours we decided to prolong the waiting period to 7 hours. Similarly we also increased the dosage of tetanus antitoxin from 200 times the neutralizing dose to 300 times, because our experience in the past has shown that the dosage of antitoxin must be proportionately increased with the time interval if the animal is to be saved. To 3 dogs therefore we gave 100 D.L.D. of tetanus toxin intravenously and at 7 hours gave in a similar manner 300 times the neutralizing dose of tetanus antitoxin. The course of these animals was uneventful until the third day when all 3 developed stiffness of the back and hind limbs (ascending tetanus was not uncommon in our experience). In 2 of the animals the signs did not progress, however in 1 opisthotonos with inability to stand developed on the fourth day. The signs in this last dog remained stationary after the fourth day and seemed to be improving but the animal was found dead on the morning of the sixth day. Of the 2 other dogs 1 developed distemper

and was sacrificed on the fourteenth day because of its poor condition. The remaining dog gradually lost the spasticity and was in excellent condition when sacrificed 3 months later. Histological examinations of the kidney and liver were normal. There was, however, considerable thickening of the dura with mild infiltration of arachnoid, but the anterior horn and cortical cells appeared to be normal. We concluded from these experiments that dogs can frequently be saved when 300 times the neutralizing dose of tetanus antitoxin is administered intravenously 7 hours after the intravenous injection of 100 DLD of tetanus toxin, although signs of tetanus may develop. We must assume that some of the toxin was so fixed within 7 hours that 300 times the neutralizing dose of antitoxin could not inactivate it. The histological study of the surviving animal which was sacrificed 3 months later revealed that most of the pathological changes induced by tetanus toxin were reversible.

SUMMARY AND CONCLUSIONS

- 1 Intrathecal administration of phenol to dogs given intravenously 100 DLD of a tetanus toxin known to kill healthy dogs within 25 to 26 hours, will not prevent death of the animals. If anything, their death is hastened by the additional central nervous system damage or lowered resistance to disorder which phenol apparently produces. The administration of tetanus antitoxin in sufficient amounts does save the dogs when given within 6 hours of a similar dose of toxin.
- 2 The lethal dose of a 10 per cent phenol solution for dogs was found to lie between 0.3 and 0.35 gram per kilogram of body weight when given intravenously. The damage to the kidneys and livers was in direct proportion to the amount of phenol given.
- 3 Intravenous 10 per cent phenol in the dosage used, given simultaneously with 100 DLD of tetanus toxin through opposite veins, did not alter the progress of the tetanus and the bio assays did not reveal any detoxifying effect of the phenol.
- 4 Intravenous 10 per cent phenol in the dosage used given simultaneously with 10 DLD of tetanus toxin through opposite veins, did not alter the progress of the tetanus

and the bio-assays did not reveal any detoxifying effect of the phenol.

- 5 The common preservatives used in tetanus antitoxin are definite irritants to the central nervous system. Tetanus antitoxin containing these preservatives should not be used intrathecally in the treatment of tetanus.
- 6 Dogs given 100 DLD of tetanus toxin intravenously were saved when given at 6 hours between 182 and 200 times the neutralizing dose of tetanus antitoxin.
- 7 Dogs given 100 DLD of tetanus toxin intravenously were saved when given at 7 hours 30 times the neutralizing dose of tetanus antitoxin, although signs of tetanus developed. It was suggested that in 7 hours a portion of the injected tetanus toxin was so irreversibly fixed that it could not be neutralized by the dosage of antitoxin given.

The authors wish to express their appreciation to Dr F H Lewis, Dr Harold M Dixon for their help in the study of our pathological specimens and to Dr I S Ravin and Dr J S Lockwood for their encouragement and counsel so wisely given.

ECLAMPSIA AND POSTECLAMPTIC HYPERTENSION

A Follow up Study with an Analysis of Factors Affecting the Remote Prognosis

LEON C. CHESLEY Ph.D. and ILLARD H. SOMERS M.D. Jersey City New Jersey

IN the present paper we shall present an analysis of a large series of postclamptic women. Of the 167 patients who were treated in 169 eclamptic pregnancies in the whole experience of the Margaret Hague Maternity Hospital 165 or 98.8 per cent, are either dead or have been re-examined recently. In addition 20 women living had eclampsia elsewhere have been examined. We shall describe the incidence of hypertension and proteinuria, the results of re-function tests, the everground findings, and general cardiovascular status at follow-up. In analysis will be shown of the several factors in pregnancy conceivably affecting the remote prognosis. Fetal mortality has been examined for the elements which seem to be of relative importance.

As early as 1851 Frenchs stated that eclampsia not infrequently is a rise to chronic nephritis. Many who especially in Germany have supported this opinion, while others have discounted. Reviews of earlier publications and refers to the literature have been given by Knick (1894) Schultz (1932) Bell (1932) Jentoft and Major (1936) and Browne and Addis (1939). In summarizing the earlier positions, Bell concluded that a mild degeneration in the renal blood vessels may often present after eclampsia.

Whether the renal lesions be hypertension found after eclampsia be attributed to the toxemia is not entirely clear for at least two reasons. (1) In some of the vascular disease and hypertension antedated the eclampsia, as Teel and have recently emphasized. (2) In many of the follow-up studies, postclamptic patients have been re-examined 15 to 20 years after the eclampsia. As Volhard has said of hypertension, "the

only etiological factor about which there can be no doubt is age." Without accurate determination of the incidence of hypertension in postclamptics within periods too short for other factors significantly to affect the incidence and without a suitable control series—almost never provided—it is hard to say that a hypertension found so many years after eclampsia has been caused by the toxemia.

Estimates of the frequency of permanent hypertension after eclampsia range from 0 to 78 per cent with all intermediates, and with very few authors agreeing upon even the approximate incidence. Table I summarizes much of the published literature. A study of this table reveals that most investigations have been made by re-examining only a small proportion of the eclamptics originally observed.

Possible reasons for the wide discrepancies may be classified as: (1) Often a fair sampling of the postclamptic population has not been made. (2) The majority of studies have been made with fewer than 50 patients. (3) The length of follow-up varies greatly. Furthermore the incidence of hypertension increases with age in women as well as in men, and also the question of slow healing of the vascular lesions with the eventual disappearance of hypertension has a bearing upon the problem of the frequency of sequelae.

Hegnemann and others have shown that after eclampsia many patients with residual hypertension gradually improve. On the other hand, Peckham re-examined post eclamptics at 13 months and again at about 6 years after delivery and found that the incidence of "chronic nephritis" had increased from 23 per cent to 37.7 per cent. It would seem, therefore, that variations in the time intervals of follow-up observations will affect the incidence found for hypertension.

TABLE I—SUMMARY OF THE LITERATURE DEALING WITH THE SIGNIFICANCE OF ECLAMPSIA

fetuses of less than 1000 grams be subtracted the mortality would be 25.6 per cent.

Since there were 8 sets of twins, we have 177 babies to account for. Of these, 118 were discharged alive, 17 were stillborn, and 12 were neonatal deaths. The frequency distribution of the fetal weights and duration of pregnancy with an analysis of the survival in each group is summarized in Table II. As the pregnancy progresses and the fetus becomes larger, the rate of survival increases rapidly. Much of the adverse effect of eclampsia upon the baby, would seem to be in the premature delivery. Yet most of the deaths are not neonatal deaths in which prematurity might be expected to be operative. The great majority, 79.6 per cent, of the babies lost are stillborn. Hence it seems that the older the fetus, the more resistant it is to whatever intrauterine factor is so often lethal.

Extrauterine existence costs fewer infant lives than does continued intrauterine exist-

ence. This is true of all age groups and for all weight groups except those below 2000 grams. Of 144 babies born after thirty-fifth week, 28 or 19.4 per cent, were stillborn. Of the 116 born alive, 4, or 3.45 per cent, died. Assuming the death rate to remain constant, delivery at thirty-fifth week would have saved 23 infant lives—could the eclampsia have been foreseen.

In carrying a toxic patient to secure an older and heavier baby, with consequent lower neonatal mortality, we postulate that the babies be born alive. It is important, therefore, to learn what will be the effect of continuing maternal toxemia upon the baby still *in utero*. A dramatic answer to this question is given in Table III. When delivery is delayed more than 3 days after the first convulsion, 57.2 per cent of the fetuses die *in utero*. Delivery within 3 days shows a stillbirth rate of 25.5 per cent—less than half that seen in cases delivered later. In postpartum eclampsia only 2.2 per cent are stillborn.

FOLLOW UP FINDINGS

Hypertension Table IV summarizes our material and sets forth the incidence of hypertension found in the recent re-examinations. Counting the 5 relevant remote deaths, the incidence of outright hypertension—blood pressure above 140/90—is 17.52 per cent. If we include as hypertensives those patients with elevated systolic pressure only and those with increased diastolic pressure only then the incidence becomes 27.28 per cent. The average incidence of hypertension for 1,454 post eclampsics as summarized from 41 publications (Table I) is 19.88 per cent—chronic nephritis counted as hypertension.

The average blood pressure, at follow-up in our patients is 124/81 millimeters of mercury (Table V)

TABLE V—AVERAGE BLOOD PRESSURE

	Mean	Probable error	Standard deviation	Coefficient of variability
Systolic	124.64		19.76	84
Diastolic	80.9	78	1.30	10.1

The average age at follow up is 29.75 years, for those with hypertension the average age is 34.30 years, and for those with normal blood pressure it is 28.50 years. For the patients who showed systolic elevations only or diastolic elevation only the average age is 27.89 years. Perhaps some of these patients, when older will be outright hypertensives, perhaps in others the residual lesions will heal, and they will be normal. For convenience, these will henceforth be called 'half hypertensive'.

The average length of follow-up was 48 months for the patients having hypertension, and 52 months for those with normal blood pressure, the range for both groups is from 5 to 103 months (Margaret Hague Hospital series). In the series of women who had had eclampsia elsewhere, the average follow-up was 13 years and ranges from 4 to 27 years.

The proportion of patients with increased blood pressure is slightly lower among those who had eclampsia before 1935 though the follow-up is, of course longer. This difference is not statistically significant, for analysis by

the chi² method reveals that there are 48.6 chances in 100 for the difference to arise by a sampling error alone. Since the incidence of hypertension in these two groups is similar it might appear that post eclamptic hyperpnea is manifested soon after the toxemia. It would then follow that re-examinations made many years after eclampsia are not especially advantageous in assessing the remote effects of the toxemia. In fact the interpretation of such long term follow-ups is complicated by the increasing incidence of hypertension in any group of older individuals. This factor of age may account for the higher incidence of hypertension which we have found in the 20 women who had had eclampsia in other hospitals. In this group the average age at follow-up is 35.4 years, the incidence of hypertension is 50 per cent.

We have used 3 control series of women from the literature. Wetherby has made a study of the blood pressure distribution in 3,258 women visiting the out patient clinic in Minneapolis only cases of definite glomerulonephritis and aortic insufficiency were excluded. Blood pressures were taken with the patient sitting after having waited for some time in the clinic. Of this series, 1,544 women were in the age groups represented by our patients at follow up. The second control group is that of Alvarez and Zimmermann for 216 unmarried women drawn from the office practice of Alvarez, in California. Blood pressures were taken with the subjects recumbent, after some rest, and either the lowest or the modal pressure of several readings was accepted.

The third control series is that of Saller who analyzed the blood pressures of 1,743 women attending the out patient clinic at Kiel 99 per cent of these subjects were of the laboring class. Patients excluded from the analysis were those with recognizable renal disease, anemia, hormonal disturbances, and diabetes. Blood pressures were taken after the patients had waited at least half an hour in the clinic. Of Saller's series, 1,142 women were in the same age groups as our post eclamptics.

The age groups of these various control series were weighted so as to correspond with the age distribution in the post eclamptic

women, and the data of the three series were combined. The corrected frequency curves were then drawn in Figure 1, which also compares the blood pressures found in our post-eclampsics. The 3 curves drawn from the published data of the authors cited are strikingly similar, for the systolic pressure and are very nearly parallel over the whole range of blood pressures observed. The diastolic curves are not in such good accord. These data, then, give a fair index of the frequency of increased blood pressure in a large group of women (2,902) who are living under diverse conditions.

As one compares the control curves with that for the post-eclamptic women, it is apparent that there is a slightly increased incidence of hypertension among the patients who have had eclampsia. Of all the control series, Wetherby's shows the highest proportion of women with elevated blood pressures. Accordingly, this series has been taken for comparison in analyzing the statistical significance of the findings in the post-eclampsics (Table VI).

TABLE VI—CONTROL SERIES, CORRECTED FOR AGE

	Systolic greater than		Diastolic greater than	
	140 mm Hg	150 mm Hg	90 mm Hg	100 mm Hg
	Per cent	Per cent	Per cent	Per cent
Wetherby	14.84	8.25	20.7	5.1
Alvarez and Zimmermann	16.76	5.56		
Saller	6.89	2.67	6.51	1.1
Posteclampsics	18.0	13.1	23.4	13.1

It is only at pressures above 150 systolic and 100 diastolic that the post-eclampsics show significantly higher incidences than do Wetherby's women.¹

We may conclude, then, that there is an increased incidence of hypertension among

¹Dividing each of the series at these pressures constructing four fold tables and solving for χ^2 in order to get the probabilities we find that there really is a significant difference in the control and post-eclamptic groups. There are only 4 chances in 100 that the difference between Wetherby's corrected curve and the curve for the post-eclampsics could arise by sampling error—considering the portion beyond 150 millimeters of mercury for the systolic pressure. For the curves below diastolic pressures of 100 millimeters of mercury, there are but 63 chances in 100,000 that sampling errors could give the difference.

post-eclamptic patients, this difference is statistically significant.

Proteinuria In 123 of the 159 patients, or 77.2 per cent, no protein was found in the urine. A very faint trace was detected in 32, or 20.2 per cent. As mentioned, the sulfosalicylic acid method was used. By the boiling and acetic acid test, the great majority of these urines would have been negative. Moreover, voided specimens were taken for the analysis. Short and Ley have recently demonstrated as much or more urinary protein in 20 to 31 per cent of nearly 5,000 women in life insurance policy holders. We believe therefore, that no significance can be attached to the minimal amounts of urinary protein in these 32 post-eclamptic subjects.

One patient, with a normal blood pressure at 97 months after eclampsia and her last delivery, showed a trace of protein in a voided specimen. Another, A. E., whose case is described under the remote deaths, had a 2 plus (about 3 grams per liter) proteinuria. The third patient to have a proteinuria of significant degree is described under the remote deaths (R. T.). She ran 8 to 10 grams per liter of protein until going into terminal uremia, she was the only patient to show urinary casts in significant numbers. In this case, renal disease was known to have antedated the eclamptic pregnancy.

In summary, only 3 patients had proteinuria of possibly significant degree. One of these was a chronic nephritic before her pregnancy, and one was probably a chronic hypertensive before eclampsia.

Urea clearance Urea clearances were done in 131 cases at follow-up. An additional 21 patients attained urinary specific gravities higher than 1.025 in casual urines, since protein and sugar were absent, urea clearances were not done because they would have been normal.

In only 5 cases was the clearance found to be less than 60 per cent, and therefore subnormal. In 2 of these, hypertension without proteinuria was also found. One patient was the remote nephritic death (R. T.). In the 2 others, the lowered urea clearance was the only positive finding, and perhaps repetition of the test would give normal readings. In

any normal subject the urea clearance does occasionally fall below 60 per cent in the wide variations which may be observed.

The average clearance is somewhat lowered, both in patients with normal blood pressure and in the hypertensives (Table VII). Possibly the average would have been closer to the ideal 100 per cent if clearances had been done on the patients with high urinary specific gravities, for with their omission there is a factor of selection.

TABLE VII.—UREA CLEARANCE

	Cases	Mean, as per cent of average normal	Standard deviation
Patients with normal blood pressure	91	86	16.86
Hypertensives	26	84	8.7

Blood chemistry. For want of space we shall merely say that the blood levels of non-protein nitrogen, urea nitrogen and uric acid were always found to be within normal limits except in the case of the remote nephritic death (R. T.)

The blood sugar was pathologically increased in 3 cases. In 2 of these blood sugars were normal at the time of the eclampsia and in the puerperium. Diabetes had become manifest in the interim.

Physical examination. Of the 38 hypertensive patients seen at follow up 19 had cardiac enlargement either by physical signs or by x-ray examination. Of these, 2 cases were associated with rheumatic heart disease. Eight of the patients had signs and symptoms of cardiac insufficiency. One was admitted to the hospital during the course of the follow up in cardiac failure with the diagnosis of hypertensive cardiovascular disease.

Special interest was attached to the eye ground findings since their importance has been emphasized by Corwin and Herrick and by others as substantiating the nature of the hypertension following toxemia. Of the 38 hypertensive patients 26 had satisfactory eye ground examinations. Four had died with no record of fundus readings 3 were not examined because they were seen in the home and in 2 the pupils were too contracted for satisfactory examination. Since the patients were unac-

companied to the clinic, in many cases, dilatation of the pupils was omitted.

Of the 26 examined 23 had definite eye ground changes. In 19 this consisted of attenuation of the arterioles with or without irregularity of the lumen. In 4 irregularity of the arteriolar lumen was noted, although the arterioles in general were of average caliber as compared with the veins. In 9 patients compression of the vein at the arteriolar crossing was noted. The light reflex was so increased in 9 patients as to excite a special note. In 2 the wall of the attenuated artery looked unusually heavy with the lumen reduced to a thready line. In 1 patient hospitalized in cardiac failure edema of the discs appeared and in another "albuminuric retinitis" with exudate and hemorrhage was seen. Marked choroidal change was present in 2 instances.

The findings in the half-hypertensive group of 11 patients confirmed our impression that these included a high percentage of cases which would become outright hypertensive cases on later examination. Of the 8 patients investigated for fundus changes, 4 showed abnormalities: 2 had irregularity of the arteriolar lumen and 2 general attenuation of the arterioles.

Among the patients with normal blood pressure there were 4 instances of significant eyeground changes. Two had thickening of the arteriolar walls, increased light reflex but no irregularity in caliber. Two showed irregularity of the arterioles without change in the general caliber of the vessels.

The radial arteries were palpated in each case, but it was not felt that any information about the state of the vascular system was obtainable in this way, which could not be more reliably ascertained by other means.

In 7 patients still surviving the full blown picture of high blood pressure, radial artery sclerosis, eyeground changes, and cardiac enlargement was present.

FACTORS AFFECTING THE PERSISTENCE OF HYPERTENSION

In analyzing the elements which seem to contribute to the persistence of hypertension, we find that some are amenable to control,

strated the incidence of postclampic hypertension increases with the parity of the patients.

TABLE XII—PARITY

Parity	I	II	III	IV and more
No cases	60		39	34
Per cent hypertensive			39	47
Per cent half by perimenstrum	8	8		
Per cent normal	7	78	57	47

Since in general the patients of higher parity are older we have tried to separate the factors of age and number of births, though there are not enough cases to give clear-cut results in all age groups. The analysis, shown in Table XIII, indicates that parity, independently of age, seems to be a governing factor in the persistence of hypertension. However this may in turn be explained by the occurrence of other toxemias in some of the pregnancies.

Time of onset and duration of toxemia. As has been pointed out in the introduction, two factors—time of onset and duration of toxemia—have not been hitherto separated in analyzing their influence upon the finding of hypertension at follow-up examination. It is especially important to make this differentiation

TABLE XIII.—RELATION OF PARITY INDEPENDENTLY OF AGE, TO SUBSEQUENT HYPERTENSION AFTER ECLAMPSIA

Status at follow-up		Age	Hypertensive	Half by perimenstrum	Normal
Age	Parity	No.	Per cent	Per cent	Per cent
21	II		16	16	56
20-30	I	30		30	90
	II	17		17	83
	III		23		77.5
	IV+	3	37		60
40	I		16	8	73
	II		20		80
	III		30		90
	IV+				87
41+	I, II, III,		42.5	26.5	86
	IV and more		80	30	90.5

tion because it has a self-evident bearing upon the treatment of antepartum eclampsia.

In 1878 Schroeder suggested that the longer a patient was carried with toxemia, the more likely she was to have a chronic nephritis later. Perhaps the first to publish quantitative studies on the question was Gibberd. He found that in 38 previously normal women, in whom pregnancy was terminated within 3 weeks after the appearance of toxemia, only 5 per cent developed "chronic nephritis." Among 29 previously healthy patients in whom the toxemia was allowed to continue for more than 3 weeks 38 per cent developed signs of "chronic nephritis." The recurrence rates of toxemia in subsequent pregnancies were 36 and 76 per cent, respectively. Regarding the fact—as Gibberd did—that patients carried for longer periods must often have earlier onsets of toxemia, it seems logical to consider that exposure of the vascular system, including the blood vessels of the kidney to continuing toxemia may cause progressive damage. The hypertension found at follow-up then might be said to be caused by the toxemia.

When toxemia onset is considered without regard to its duration, early appearance seems to be associated with an increased incidence of hypertension at follow-up. Disregarding the duration of toxemia the gross incidences of

TABLE XIV.—ELEVATED BLOOD PRESSURE AT RE EXAMINATION

Toxemia onset	Follow-up findings		
	Hypertensive Per cent	Half-hypertensive Per cent	Normal Per cent
Before seventh month	44		57
Seventh to eighth month	30	30	60
Eighth to ninth month	20	1	77.5

TABLE XV.—DURATION OF TOXEMIA

Duration of toxemia	Follow-up findings		
	Hypertensive Per cent	Half-hypertensive Per cent	Normal Per cent
Less than 3 weeks			77
More than 3 weeks	47.7		47.7

TABLE XVI—RELATION OF DURATION OF TOXEMIA TO SUBSEQUENT HYPERTENSION

Findings at follow up	Onset of toxemia					
	Before 7th month		7th-8th month		8th-9th month	
	Carried with toxemia					
	Less than 3 weeks	More than 3 weeks	Less than 3 weeks	More than 3 weeks	Less than 3 weeks	More than 3 weeks
	Per cent	Per cent	Per cent	Per cent	Per cent	Per cent
Hypertension	14.3	63.6	0.0	60.0	10.3	12.5
Half hypertension	14.3	0.0	20.0	20.0	12.0	25.0
Normal	71.4	36.4	80.0	20.0	77.7	62.5

elevated blood pressure at the re-examination are shown in Table XIV. Similarly when the duration is considered alone, an increased incidence of hypertension parallels longer duration (Table XV).

However, when we examine in each case the effect of onset in terms of the duration of the toxemia, as in Table XVI, it is seen that the important factor of the two is duration of the toxemia, the time of onset, *per se*, does not significantly affect the remote prognosis. When the toxemia appeared in the seventh month, a high proportion of patients were carried for several weeks before delivery, in the interests of the fetus. This longer average duration of toxemia masks the fact that a patient having toxemia appearing in the seventh month—if promptly delivered—is no more likely to have permanent hypertension than is the woman who has toxemia appearing at term.

Severity of toxemia. Our data accord with what several previous writers have pointed out, a definite correlation can be drawn between the severity of the eclampsia and the incidence of subsequent hypertension. When the systolic blood pressure, in eclampsia, averages less than 180 milligrams of mercury, 10.66 per cent of the patients had hypertension at follow-up. The level of blood pressure and degree of proteinuria, below this point, do not seem to influence the appearance of persistent hypertension. In those cases in which the systolic blood pressure, during eclampsia,

averages more than 180, the incidence of persistent hypertension jumped to 44.8 per cent (Table XVII).

TABLE XVII

	Blood pressure less than 150		Blood pressure 151-180		Blood pressure 181-200		Blood pressure more than 200	
	Proteinuria	Proteinuria	Proteinuria	Proteinuria	Proteinuria	Proteinuria	Proteinuria	Proteinuria
	<2+	>2+	<2+	>2+	<2+	>2+	<2+	>2+
No cases	23	24	17	58	2	19	1	7
Per cent hypertensive	13.05	16.67	5.89	8.62	0	47.4	100	42.9
Per cent half hypertensive	4.35	8.33	5.89	12.07	0	15.8	0	28.6
Per cent normal	82.60	75.00	88.22	79.31	100	36.8	0	28.6

Blood pressure and proteinuria at 10 days and 6 weeks postpartum. Future hypertension cannot be predicted with any confidence from the blood pressure and urinary protein findings at 10 days or at 6 weeks after delivery. However, patients who have not returned to normal within this period are considerably more liable to subsequent hypertension (Table XVIII).

TABLE XVIII

	No cases	Hypertension in follow up Per cent
Blood pressure normal at 10 days	99	13.13
Blood pressure high at 10 days	58	37.02
Blood pressure high at 6 weeks	15	46.70
Proteinuria less than 2 grams per liter at 10 days	107	11.22
Proteinuria more than 2 grams per liter at 10 days	41	46.30

Weight/height ratio at follow-up. Hypertension generally is more common in individuals who have high weight/height ratios, i.e. in the obese. The incidence of hypertension in our post eclamptics shows this same relation to obesity (Table XIX).

TABLE XIX—WEIGHT/HEIGHT RATIO

Weight/height ratio	No cases	Hypertension Per cent	Half hypertension Per cent	Normal Per cent
Less than 1.80	22	4.5	0	95.5
1.81-2.60	77	13.0	7.8	79.2
More than 2.61	23	30.4	26.1	43.5

TABLE XX—RELATION OF SUBSEQUENT PREGNANCIES TO THE INCIDENCE OF POST ECLAMPTIC HYPERTENSION

Subsequent pregnancies	Cases	Status at follow up					
		Hypertensive		B.M. hypertension		Normal	
		Cases	Per cent	Cases	Per cent	Cases	Per cent
None	37		30.5	7	6	65	71.8
One	43		24.6	3	10	36	
Normal			6		6	37	87.4
Toxic	27	1	3.6		17		61.8
Two			26				34.3
Both normal			8		16		3
One normal One toxic	6	3	50				37
Both toxic	3		80				30
Three			60			6	60
Four	4	1	25				7

Since weight reduction in overweight patients will often reduce the blood pressure (Ley) it would therefore seem that the control of obesity might be of value in post eclamptic patients.

Subsequent pregnancies One of the most practical questions arising for the remote prognosis in a patient who has had eclampsia is that of further pregnancies. We have seen many post eclamptic patients in whom no abnormality can be found and who have been warned against any further pregnancy. In a few cases therapeutic abortions have been done (elsewhere) because of the eclamptic history alone. Many publications lend support to these steps.

We have made an analysis of the 84 post eclamptic patients who have had subsequent pregnancies, and compared them with the 92 patients who have had no later pregnancy.

From the data in Table XX, it appears that one or two subsequent normal pregnancies will not affect adversely the remote prognosis. A subsequent toxic pregnancy, however, will increase markedly the chances for a persistent hypertension.

It is interesting to note that if one subsequent pregnancy occurs, and if it is toxic, the incidence of hypertension at follow-up is

about 50 per cent. When 2 subsequent pregnancies occur 1 normal and 1 toxic, the normal pregnancy does not seem to count, and the toxic pregnancy exerts its same effect—the incidence of hypertension is again found to be about 50 per cent.

We have made an analysis of the effect of all pregnancies, before and after eclampsia. Since the incidence of hypertension is lowest among patients who have had only the one (eclamptic) pregnancy and almost equally low among those whose other pregnancies have been normal, it seems that *perhaps the most important single factor in determining future hypertension is another toxemia (Table XXI)*.

TABLE XXI

Follow up finding	No other pregnancy	Other pregnancy normal	Other toxemia known	Other toxemia	
				Known	Unknown
No cases	33	45		47	3
Per cent hypertension	6.6	8.9	30.8	44	6
Per cent h.M. hypertension	8.6				
Per cent normal	21.9	9.3	64.2	47.3	37.3

The incidence of hypertension is so low in post eclamptic patients who have had no other toxemia, that we may question whether eclampsia alone does cause remote hypertension. Taking the data at face value it might seem that eclampsia merely predisposes the patient to toxemia which in turn causes the hypertension found at follow up. Of the 38 post eclamptic hypertensive patients, 26 or 68.4 per cent, are known to have had at least one other toxic pregnancy, 8, or 21 per cent, are known not to have had another toxemia and in 4 cases this is uncertain.

RECURRENCE OF TOXEMIA

Of all the post eclamptics, 90 patients have had 143 subsequent pregnancies 26 or 18.17 per cent of these terminated in abortions 16 or 11.18 per cent, in stillbirths and 101 or 70.65 per cent, in live births. Thus the fetal losses in later pregnancies almost exactly match those present in the eclamptic pregnancy group.

Thirty-seven of the 84 patients carrying their pregnancies past the twenty-fourth week had 55 toxemias, or 47 per cent, of which 2, or 2.38 per cent, were again eclamptic. The published data from Table I show 881 women pregnant after eclampsia, with a toxemia recurrence of 39.3 per cent. However, many of these papers do not include mild toxemias, but only count recurrent eclampsia and severe toxemia.

Prenatal care did not seem to avail much in reducing the rate of recurrence in toxemia, though the incidence of severe toxemia is probably diminished by such care (Table XXII).

TABLE XXII — PRENATAL CARE

	No care	Private care	Clinic care	
			Less than 2 mo	More than 2 mo
Pregnancies	11	31	28	46
Toxic, per cent	54.5	48.4	53.5	41.3

The age of the patient at the time of eclampsia is directly related to the recurrence of toxemia in subsequent pregnancies (Table XXIII).

TABLE XXIII — AGE WHEN ECLAMPTIC

	15-20	21-25	26-30	31-35	36-40
Recurrence of toxemia per cent	37.15	41.95	55.60	71.50	100

The severity of the eclampsia affects the recurrence rate of toxemia in later pregnancies (Table XXIV).

TABLE XXIV

	Average blood pressure in eclampsia			
	Less than 150 mm	151-180	181-200	More than 201
Pregnant again	29	7	8	2
Toxic in later pregnancy per cent	20.7	48.1	62.5	100

We cannot assess the influence of time of onset and duration of toxemia independently, because we have too few cases in which the necessary data are known. However, in 66 cases (51 patients) we do know the duration

of toxemia in the eclamptic pregnancy. As shown in the analysis, any patient carried with toxemia for more than 2 weeks is more likely to suffer later toxemia (Table XXV).

TABLE XXV

Duration of toxemia in eclamptic pregnancy	Subsequent pregnancies	Toxemias per cent
Less than 2 weeks	39	70.5
More than 2 weeks	27	63.0

Subsequent pregnancy, to restate an idea current in the literature, is a delicate test of the damage left by a toxemia. While the severity of the eclampsia does affect the remote incidence of persistent hypertension, the effect is more clearly seen in the recurrence rate of toxemia. Similarly, duration of toxemia affects the later appearance of hypertension, but toxemia of even shorter duration has an equally marked effect upon the recurrence of toxemia.

It is a common practice to warn post-eclamptic patients against having another pregnancy "too soon." This serves to cut down the total number of pregnancies, which is beneficial as we have seen above. This recommendation also carries the implication

TABLE XXVI

	Interval from eclampsia to conception					
	Less than 3 months	3-6 months	7-12 months	13-24 months	25-36 months	More than 36 months
No pregnant again	4	7	14	18	16	14
Per cent toxic in first pregnancy after eclampsia	50	71.5	64.2	55.7	31.2	50.0

that after eclampsia the damage inflicted may heal gradually. On the basis of the few cases available we have sought for a relationship between the interval from eclampsia to conception and the recurrence of toxemia. There seems to be a rough trend to indicate that the longer the interval, the less the chance of having a recurrent toxemia (Table XXVI).

SUMMARY AND CONCLUSIONS

The immediate maternal mortality, in a series of 169 cases of eclampsia, was 7.10 per cent, uncorrected.

The fetal losses, including all cases were 33.5 per cent. The chief source of fetal loss is stillbirth. The factors contributing to the death rate are prematurity and duration and severity of the maternal toxemia.

An analysis is presented of the eclamptic pregnancies as a basis for an assessment of the effects of various factors in pregnancy upon the persistence of hypertension.

Of the 155 women surviving eclampsia, 8 have died subsequently. 5 deaths were in the field of cardiovascular and renal disease.

The incidence of hypertension at follow up in the Margaret Hague Maternity Hospital series, was 17.5 per cent in the women who had had eclampsia elsewhere it was 50 per cent. An additional 9.8 per cent of the former had a systolic or a diastolic elevation alone.

The incidence of hypertension among the post-eclamptic patients is significantly greater than in the female population at large, correction being made for age distributions.

The incidence of proteinuria of significant degree is 2.6 per cent at follow up.

Renal function as measured by the urea clearance and urinary specific gravity is in the normal range in at least 97 per cent of the patients at follow-up.

The majority of the living hypertensives had significant eyeground findings. Half had cardiac enlargement and 8 had signs and symptoms of cardiac insufficiency.

An extensive analysis has been made of the factors contributing to the persistence of hypertension. In general we may say that high blood pressure is more likely to be found at follow up if there is antecedent renal or vascular disease. Also the higher the first observed blood pressure in pregnancy—even in the normal range—or the older the patient when eclamptic or at follow-up or the more children she has had or the longer she is carried with toxemia, or the more severe the eclampsia, or the more obese the patient, the more likely hyperplasia is to persist. The time of onset of toxemia, whether in the seventh month or at term, has no direct effect upon the remote prognosis. Early onset often seems to favor future hypertension only because the patients are carried for considerable periods before delivery.

None of the above considerations is so decisive in conditioning remote hypertension as is recurring toxemia subsequent to the eclampsia. Hypertension is not often found in a woman who has had a single eclampsia as the only toxemia of pregnancy. Most of the post-eclamptic hypertensives have had an other toxemic pregnancy.

The recurrence rate of toxemia in pregnancies after eclampsia was found to be 47 per cent. In general, the factors enumerated above which favor the persistence of hypertension favor in even greater degree the recurrence of toxemia.

After the thirty-fifth week of gestation, the fetus fares much better *ex utero* in eclampsia.

In subsequent pregnancies after eclampsia the fetal losses were 29.4 per cent.

Advising against future pregnancies in a post-eclamptic would seem to be justified by the recurrence of toxemia in 47 per cent of cases, with a consequent 8 fold increase in chances for permanent hypertension if the pregnancy is toxic.

In evaluating a given patient's risks in a future pregnancy one may consider the present blood pressure, the severity of the past eclampsia, duration of that toxemia, obesity, age, and interval since the eclamptic pregnancy.

We wish to express our grateful appreciation to Dr. S. A. Conger, for his painstaking criticism of this paper. Drs. J. F. Norton and E. G. W. tern have also made helpful suggestions. We are indebted to many physicians who have permitted us to re-examine their private patients, and to the many people who have co-operated in finding lost patients. Many of the blood and urine work examinations were done by Frances Ortol and Peter Marotta. Mrs. E. R. Chesley assisted in finding and examining patients.

A STUDY OF THE CLINICAL MANIFESTATIONS AND THE RESULTS OF TREATMENT OF TWENTY-TWO PATIENTS WITH RAYNAUD'S SYMPTOMS

CARL A JOHNSON, M D , Chicago, Illinois

THE symptom complex commonly known as Raynaud's disease has received an unusual amount of attention in medical literature since its original classical description by Raynaud in 1862 (7, 8). Little has been added to the original description or theories, however, and Lewis (6) states that, "just as Raynaud's description stands, so his views of the malady predominate today."

It was recognized early that what is known as Raynaud's disease is probably not a disease but a symptom complex, the objective manifestations of which have a multiple etiology. John Hunt, in his recent review of the subject, stated, "nearly fifty years ago Hutchinson recognized clearly the true significance of Raynaud's thesis, and in his writings he stressed the fact that, 'Raynaud's phenomenon,' as he called it, was not a clinical entity at all but a syndrome occurring in many different conditions." Hunt subscribes to this view, but believes that the term Raynaud's disease is so well established it will continue to be used whether it has any meaning or not.

One is impressed with the wide difference of opinion regarding the nature and etiology of Raynaud's symptoms, the diagnosis, and whether what is known as Raynaud's disease even exists as a clinical entity. Allen and Brown, reviewing Raynaud's 26 original cases, concluded that only 6 could be classified as having Raynaud's disease. Hunt, reviewing the same cases, concluded that only 1 of the series had Raynaud's disease, and this one was doubtful. He stated that even if Raynaud's disease exists, it must be rare.

A wide difference of opinion exists regarding the nature and cause of the vascular phenomena observed in Raynaud's attacks. Raynaud thought the spasms were due to an abnormal vasomotor tone. Lewis thinks the attacks are due to a "local fault" with normal vasomotor tone.

This confusion and difference of opinion is reflected in the modes of treatment. Persons subscribing to abnormal vasomotor tone advocate operations on the sympathetic nervous system; those thinking the spasms due to a local fault use

general measures in an attempt to avoid attacks and to correct the local fault.

Realizing the controversial nature of all aspects of the subject, it is with hesitation that I add another report which offers no solution. But this report is believed to be justified by its presentation of a new method of attack, some new ideas on the state of the vascular system, and the results of medical as contrasted with surgical management. This study involves the history, physical findings, laboratory findings, treatment, and course of 22 patients with Raynaud's symptoms in the hands, or in the hands and feet. Raynaud's symptoms never occurred in the feet alone.

To conserve space and illustrations, the detail concerned with the patients is summarized in tables. Table I is a summary of the patients' histories. Although self-explanatory, a few findings require some comment. There are two colored patients in this series: one male and one female. No reports of Raynaud's disease in the colored race could be found.

In this series, all the patients had Raynaud's symptoms in the fingers, 11 had similar symptoms in the toes, but in no case did the symptoms occur in the toes without the patient being subject to the symptoms also in the fingers. In only one of the patients with Raynaud's symptoms in the toes were the symptoms severe enough to require any particular care. A lumbar sympathectomy was done on this patient; the results are reported in detail in the case report of Mr. Y.

Emotional spells as a cause of Raynaud's symptoms are worthy of comment. In only 3 of the patients were they a frequent cause and in these 3 sympathetic surgery failed to produce any improvement as judged by recurrence of symptoms and the frequency and severity of attacks.

Table II is a summary of the laboratory findings and associated diseases. Associated diseases are comparatively common in this series: 2 had syphilis, 13, a mild secondary anemia, 2, a severe anemia, 3, stiffness of the finger joints, scleroderma, ulcers, loss of tissue, and loss of fingernails, and, 2 had sclerodactylia. It is very interesting to note that the scleroderma, stiffness of

the joints, ulcers, loss of tissue, loss of fingernails and sclerodactylia occurred in patients with the most organic vascular pathology as determined by plethysmographic studies. The manner of making these studies has been presented in a previous article (3) but illustrative records will be shown in case reports to follow.

TREATMENT

The treatment of patients with Raynaud's symptoms may be classified as follows (1) the

relief of mental anxiety (2) the improvement of an anemia (3) the treatment of any specific disease, (4) surgical treatment by operations on the sympathetic nervous system.

The relief of mental anxiety. Case 4 is striking example. Previous to the onset of the Raynaud's symptoms in December 1936, the patient had been told that she had diabetes. She continued

on a diet until she was admitted to St Luke's Hospital Out Patient Dispensary for care in October, 1937. A thorough examination revealed no evidence of diabetes. About one week after the patient had been reassured she did not have diabetes the Raynaud's symptoms disappeared. Dr. Joseph L. Miller communicated to the author the incident of a patient in whom the Raynaud's symptoms disappeared following an auto accident. It is possible the marked emotional change in these patients was sufficient to effect a cure.

The improvement of an anemia This is well illustrated by the following report.

Mrs. L. A., a white female, aged 45 years, first came under observation November 18, 1936, with complaints of typical severe Raynaud's symptoms in the first three fingers of both hands, and similar attacks in the large toes of both feet. The attacks first appeared 3 years previously in the winter and during the cold weather were so severe that she was virtually confined indoors. The symptoms were absent in the summer. She gave a history of severe uterine bleeding during and between menstrual periods. She had been advised to have this treated, but had refused because of fear of an operation. A blood count revealed the red blood cells as 3,910,000 and the hemoglobin as 45 per cent. She still refused surgery, but following intensive liver and iron therapy her blood count improved to within normal limits and as long as maintained she remained virtually free from Raynaud's symptoms even in the winter. She had only one or two attacks per month as compared to several a day before treatment. In the spring of 1939, following a hysterectomy her blood count rose further. On February 22, 1940, her red blood cell count was 5,350,000 and her hemoglobin 115 per cent. She remained free from Raynaud's symptoms the following winter.

Several patients in this series had a similar, but possibly not so striking, improvement as this.

The treatment of an underlying specific disease
The following illustrates what may be accomplished if the cause of the Raynaud's symptoms can be found.

The patient had severe Raynaud's symptoms since 1932 with associated ulcers, loss of tissue, loss of fingernails

Fig. 2 BC The effects of local heat on the skin temperatures and finger volume changes of both hands 22 days following the removal of the right stellate and second dorsal sympathetic ganglia. Note that the skin temperatures

Fig. 1 BC The effects of removal of the stellate and second dorsal sympathetic ganglia on the finger volume changes and skin temperatures of the third finger. Note the return of the finger volume changes to the pre-operative level in 21 days in spite of the fact that the skin temperature remained elevated. (From Surg., Gynec. & Obst., 1932, Dec.)

stiff joints of the fingers, scleroderma and sclerodactylia. In 1934 she was subjected to a bilateral removal of the stellate and second dorsal sympathetic ganglia, with very transient improvement. The symptoms gradually became worse. In June, 1935 antiluetic treatment was instituted. From then on she had complete relief from the Raynaud's symptoms through five winter seasons. Although the Raynaud's symptoms have been relieved completely, she has occasional ulcers on her fingers. Records taken from this patient following surgery are illustrated in Figures 6, 7, and 8.

Operations of the sympathetic nervous system
In 1932 Johnson, Scupham, and Gilbert published

on the right side are higher than those of the left even though the finger volume changes in both hands are about the same. Also note that local heat produced about the same degree of vasodilatation on both sides.

Fig. 3 T. A. The effects of removal of the stellate and second dorsal sympathetic ganglia on the body temperature, the skin temperature of the third finger of both hands, the pulse and blood pressures. The right side was used for control. Note that the body temperature and pulse did not change appreciably; that the skin temperatures of the third finger of the left, which was also true of the other fingers, remained elevated above that of the right, and that the finger volume changes increased somewhat immediately following the operation, but in 8 days returned to their former levels. A similar operation was later done on the right side.

the results of removal of the stellate and second dorsal sympathetic ganglia in one patient and indicated that the peripheral circulation was improved only temporarily in this patient thus confirming earlier experiments by others on animals. For the sake of completeness, a discussion of this first case is included with this report.

The types of operations performed were as follows: (1) unilateral removal of the stellate and second dorsal sympathetic ganglia; (2) bilateral removal of the stellate and second dorsal sympathetic ganglia; (3) bilateral removal of the stellate and third dorsal sympathetic ganglia; (4) bilateral preganglionic section of the sympathetic chain below the third dorsal ganglion; (5) removal of left stellate and second dorsal sympathetic ganglia and right preganglionic section of the sympathetic chain below the third dorsal ganglion.

The results of the studies of these patients are given as follows:

Unilateral removal of the stellate and second sympathetic ganglia. The results of the study of this patient have already been reported, but brief review is included here to show follow up studies and to correlate the findings with those of the 5 patients subsequently operated upon.

B. C. White female, aged 35 years at the time of operation, was admitted to St. Luke's Hospital on August 28, 1930. Her diagnosis of long standing rheumatoid arthritis. The early manifestations of the disease started when she was 15 years of age, but subsided and were not severe until she was 8 years old. At that time of treatment, the disease progressed until all the joints except those of the spinal column were in chronic and deformed. Reports in the literature at that time, indicated beneficial results from operations on the sympathetic nervous system. A unilateral removal of the stellate and second dorsal sympathetic ganglia, as done by Drs. Carl Hedblom and H. I. Meyer. Studies of the peripheral circulation were made before and at frequent intervals after the operation. No other therapeutic procedures were used for months following the operation so that proper evaluation of any beneficial result from the operation could be made. The patient showed no clinical improvement, but later had considerable improvement from corrective orthopedic procedures.

Figure 3 shows the marked increase of the finger volume changes immediately after the operation. The circulation had returned to the pre-operative level 21 days later although the skin temperatures of the side operated upon remained above those of the control side. Figure 4 illustrates the effects of local heat to the hands before and 21 days after the operation. This record furnishes more proof that the peripheral circulation had returned to the pre-operative

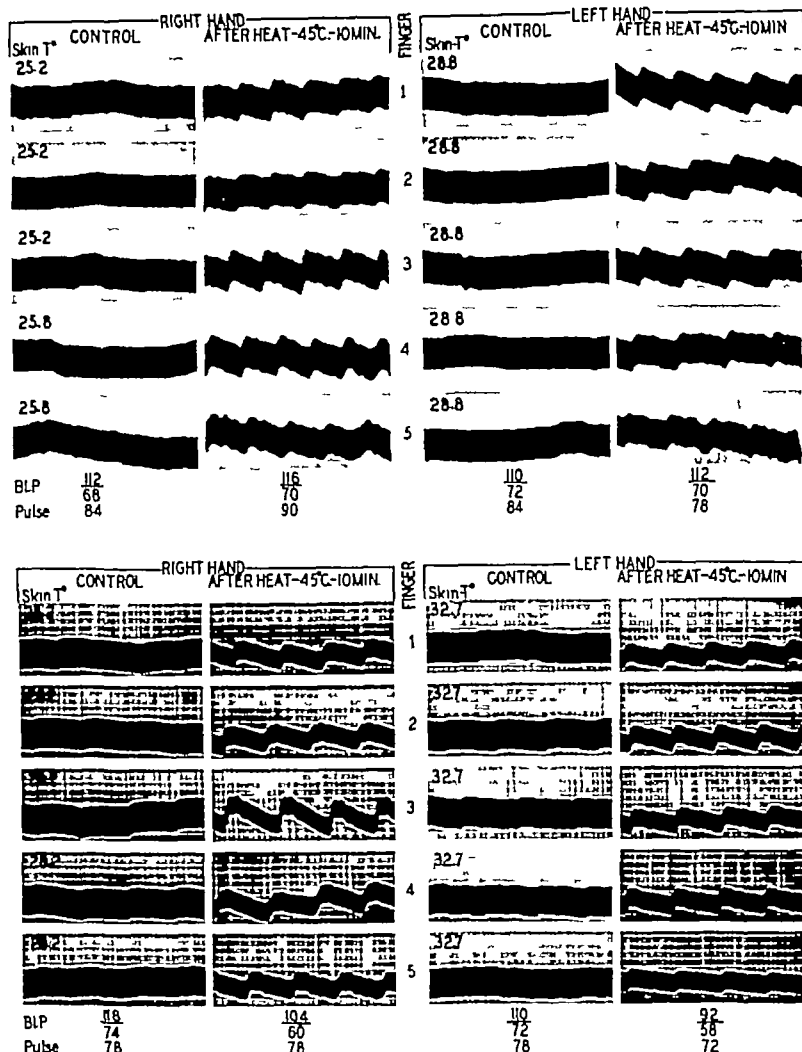

Fig 4 T A The effects of local heat to the hands before, above, and 18 days after below, operation on the blood pressures, the pulse rate, and the finger volume changes. Note that on both occasions the control finger volume changes were abnormally low and local heat caused about the same amount of increase both before and 18 days following operation. The control skin temperatures also were lower than normal. Note also the lack of correlation between the skin temperature and the finger volume changes of the left hand 18 days after operation.

level as local heat caused a vasodilatation similar to that preceding the operation.

Conclusion from this study is that the peripheral circulation returned to its pre operative level within 21 days following the operation. Further conclusions will follow presentation of 5 additional cases.

CASE 1 Bilateral resection of the stellate and second dorsal sympathetic ganglia.

T A, a white female, aged 33 years, was admitted to Passavant Hospital on March 23, 1936, on the service of Dr. Loyal Davis, for surgical relief of Raynaud's symptoms. Since November, 1932, the fingers of both hands had turned white, blue, and red, then normal. At first, only the second and third fingers of both hands had been involved to the second interphalangeal joints, later the second, third, fourth, and fifth fingers of both hands had become involved to the metacarpophalangeal joints. These attacks occurred mainly on exposure to cool air but also to cold water, and during emotional spells as well as following cold

FIG. 3. A. The effects of removal of the stellate and second dorsal sympathetic ganglia on the body temperature, the skin temperature of the third finger of both hands, the pulse and blood pressures. The right side, as used for control. Not that the body temperature and pulse did not change appreciably; that the skin temperatures of the third finger of the left, which, as also those of the other fingers, remained elevated above that of the right and that the finger volume changes increased somewhat immediately following the operation, but in 8 days returned to their former levels. A similar operation, as later done on the right side.

the results of removal of the stellate and second dorsal sympathetic ganglia in one patient and indicated that the peripheral circulation was improved only temporarily in this patient, thus confirming earlier experiments by others on animals. For the sake of completeness, a discussion of this first case is included with this report.

The types of operations performed were as follows: (1) unilateral removal of the stellate and second dorsal sympathetic ganglia, (2) bilateral removal of the stellate and second dorsal sympathetic ganglia, 2 cases, (3) bilateral removal of the stellate and third dorsal sympathetic ganglia, (4) bilateral preganglionic section of the sympathetic chain below the third dorsal ganglion, (5) removal of left stellate and second dorsal sympathetic ganglia and right preganglionic section of the sympathetic chain below the third dorsal ganglion.

The results of the studies of these patients are given as follows:

1. *Unilateral removal of the stellate and second dorsal sympathetic ganglia.* The results of the study of this patient have already been reported, but brief review is included here to show follow-up studies and to correlate the findings with those of the 5 patients subsequently operated upon.

B. C. H. female, aged 35 years at the time of operation, as admitted to St. Luke's Hospital on August 28, 1930, with diagnosis of long standing rheumatoid arthritis. The early manifestations of the disease started when she was 25 years of age, but subsided and were not severe until she was 35 years old. In spite of treatment, the disease progressed until all the joints except those of the spinal column were involved and deformed. Reports in the literature at that time indicated beneficial results from operations on the sympathetic nervous system. A unilateral removal of the stellate and second dorsal sympathetic ganglia, as done by Drs. Carl Hertzblom and H. J. Meyer. Studies of the peripheral circulation were made before and at frequent intervals after the operation. No other therapeutic procedures were used for months following the operation so that proper evaluation of any beneficial result from the operation could be made. The patient showed no clinical improvement, but later had considerable improvement from correctly therapeutic procedures.

Figure 1 shows the marked increase of the finger volume changes immediately after the operation. The circulation had returned to the pre-operative level 2 days later although the skin temperatures of the side operated upon remained above those of the control side. Figure 2 illustrates the effects of local heat to the hands before and 2 days after the operation. This record furnishes more proof that the peripheral circulation had returned to the pre-operative

Fig 6 M B Above, roentgenograms of the hands illustrating the sclerodactylia and bony changes in the terminal phalanges. Below, photographs of the hands showing scleroderma, changes in the fingernails, and loss of tissue on the ends of the fingers

tion and at frequent intervals subsequently. A similar operation was done on the right side at a later date.

Measurements of the peripheral circulation were made before and daily after the operation until the finger volume changes had reached the pre-operative level in 16 days as compared with 21 days in the previous case (Fig 3). Here, too, the skin temperatures remained higher on the side operated upon. Figure 4 shows the vasodilating effects of heat before and 18 days following the left sympathectomy. The records are similar, indicating that the vessels had regained their pre-operative tone.

Figure 5 shows the effects which were produced by median nerve block on the finger volume changes before and 17 days following the left sympathectomy. Although the characteristic numbness occurred in the first three fingers of the left hand, there was no evidence of vasodilatation. This is offered as proof of the completeness of the operation.

CASE 2 Bilateral removal of stellate and second thoracic sympathetic ganglia

M B, white female, aged 47 years. I first saw her March 13, 1935 because of Raynaud's symptoms which had been present since the winter of 1930. All her fingers turned white to the metacarpophalangeal joints. They then turned blue, red, and back to normal. She did not remember having frozen the fingers. These attacks continued and became more severe in frequency and duration. In the winter they necessitated staying indoors virtually all the time, even then she had two to three attacks daily. The attacks were caused most easily by cool air, less so by cool water. She remembered only one attack associated with an emotional upset. The attacks were relieved most easily by immersion of the hands in cold water, followed by warm water. The patient had numerous trophic disturbances and since 1931 had lost fingernails from the first, second, and third fingers of both hands. The past history was negative except for typhoid at 8 years, a rectal fistula at 25 years, and influenza at 30 years. Examination was essentially negative except for evidence of loss of tissue on the tips of the fingers, disturbance of growth of the fingernails, scleroderma, stiffness of the finger joints, and sclerodactylia (Fig 6). Dr. Loyd Davis did a bilateral removal of the stellate and second thoracic sympathetic ganglia in January, 1934. For a time the patient thought she had improved, particularly as the warm weather set in. The

Fig 5 T.V. The effects of median nerve block at the rat on the blood pressure, pulse rate and finger volume changes of both hands before above, and, below, 7 days following removal of left stellate and second dorsal sympathetic ganglia. Note that before the operation the median nerve block produced an increase of the finger volume changes and increased skin temperature of the first three fingers and less so in the fourth, while in the fifth finger there was no change. Following operation, satisfactory test could not be made because the patient became emotionally unstable. Even though satisfactory nerve block as obtained as evidenced by the numbness, the finger volume changes did not become increased.

drinks, ice cream, or chilling of the body. The attacks are more frequent and severe in winter but occurred in the summer too. There is some pain in the fingers during the white and blue stages and numbness during the red stage, which disappeared on recovery. The attacks are relieved by rubbing the hands together. Numbness disturbances are present except an ulcer on the second right finger which started in 1935 and still pains her but no pus was present. She has several attacks per day which last from 5 to 15 minutes. The past history is negative.

The physical examination is negative except for the stubby appearance of the fingers. All the peripheral vessels are easily palpable. The patient is moderately unstable emotionally and during vascular studies had hysterical attacks which sometimes lasted an hour. The laboratory findings are negative except for a basal metabolic rate. Dr. Davis removed the left stellate and second dorsal sympathetic ganglia on March 3, 1936. The right arm was studied as control. It is interesting to note that symptoms recurred 8 days following the opera-

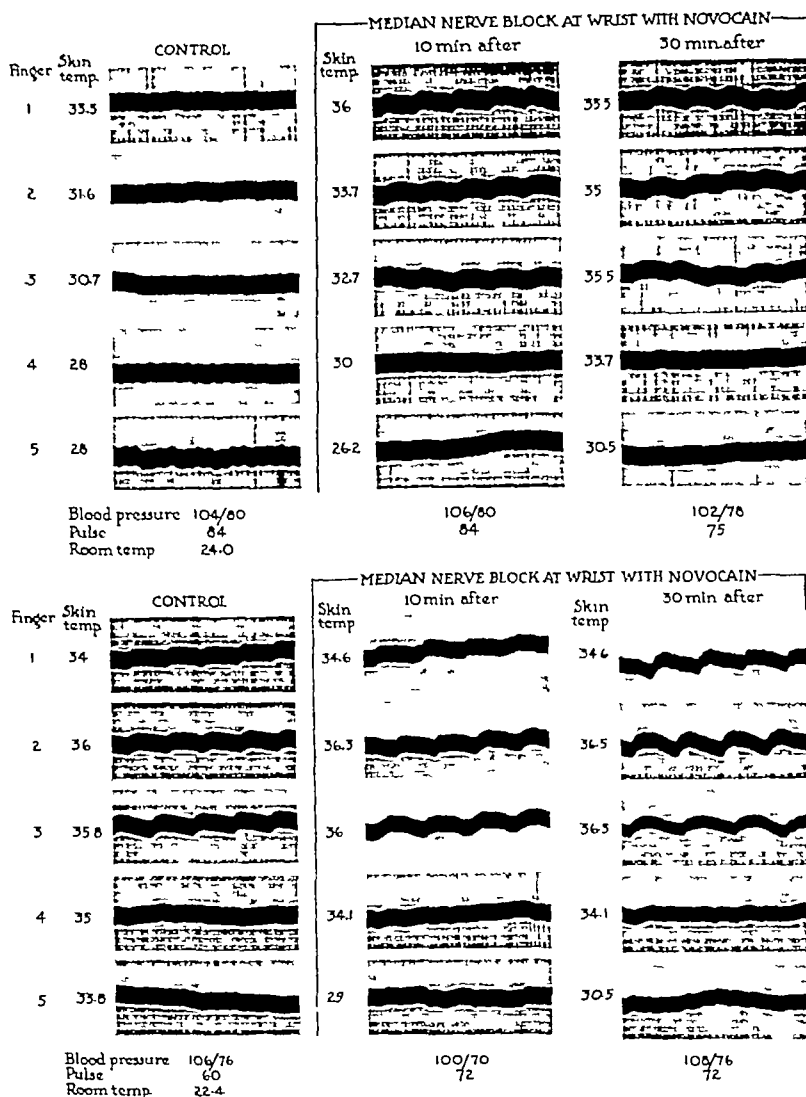

Fig 8 M B The effects of median nerve block on the finger volume changes, skin temperature of the fingers, pulse rate, and blood pressure. Note the moderate vasodilating effect of this procedure in the first 3 fingers of both hands as well as an increased skin temperature in these fingers. The finger volume changes of the fourth and fifth fingers did not change. In the fourth and fifth fingers of the right hand, below, the skin temperatures decreased, which is the usual finding in normal individuals from this procedure. Above, left hand record.

release of the vasospasm, even though theoretically, this should not occur following extensive surgery on the sympathetic nervous system. Three winters have elapsed since the operation. The Raynaud's symptoms are as severe as before the operation.

CASE 4 Bilateral pre ganglionic section of the sympathetic chain below the third dorsal ganglion.

Mr X, white male, aged 47 years, was first seen on May 25, 1937, for Raynaud's symptoms. In 1932 he noticed

that all the fingers turned white to the metacarpal phalangeal joints, then passed through the various stages of blue, red, then normal. The symptoms had their onset in the toes also at the same time as in the fingers. They were brought on most easily by cool air, chilling of the body, or during emotional attacks, but were not affected by cold drinks. During the attacks he occasionally fainted. The Raynaud's symptoms lasted from a very short time to several hours, when nothing seemed to relieve them. The

Fig. 7. M.B. The effects of local heat on the finger volume changes. Note the absence of pulsatile changes in the control records as well as no appreciable vasodilating effect of local heat particularly in the left hand, above. Bilateral removal of the stellate and second thoracic sympathetic ganglia had been done about 4 months before these records were made. Below, right hand record.

following. Inter the symptoms were as severe, or more so, than before the operation. The symptoms continued to progress in severity and duration and caused ulcers beyond the first interphalangeal joints. In June, 1936, treatment for an old syphilis was started. Since that time she has had complete relief of the Raynaud's symptoms although ulcers still occur on the fingers. The scleroderma has improved.

Studies of the peripheral circulation were made in the fall of 1935. Figure 7 shows the effects of local heat on the peripheral pulse volume changes. The small response before and after heat indicates marked organic changes in the peripheral vessels,

especially in the left hand. Figure 8 shows the effects of median nerve block on the finger volume changes. This procedure produced an improvement of the circulation in fingers innervated by the median nerve. The operation should have destroyed the vasomotor fibers traveling in the median nerve. It is difficult to understand this result unless some vasomotor fibers still remained, or somatic motor fibers may be partly vasomotor in function. The patient does not perspire in the hands or arms. It does not seem likely, however, that regeneration of the vasomotor fibers would occur without regeneration of the sweat fibers.

This case is particularly instructive because it illustrates the inadequacy of our knowledge of the sympathetic nervous system as well as the pathogenesis of Raynaud's symptoms.

CASE 3. Bilateral removal of the stellate and third sympathetic ganglia

D. L., white female, aged 49 years, as admitted to Massachusetts Hospital April 8, 1938, as patient of Dr. Loyal Davis, for the surgical relief of Raynaud's symptoms. She complained that for the past 3 years her fingers had turned successively white, blue, dark red, then back to normal. Similar symptoms did not occur in the toes. These attacks were brought on most easily by emotional spells, exposure of the hands to cold air, cool water, chilling of the body and after she drank cold drinks and ate cold foods. There was numbness but no pain during these symptoms. The attacks could occur most frequently in the winter but some took place in the summer too. They are relieved by immersion of the hands in warm water. If this is not done the attacks lasted until she overcame her emotional spell. The past history as regards except for attacks of migraine, which began at the age of 6 years and continued until she was 45 years. The menopause occurred at the age of 45 years.

The physical examination was essentially negative. Roentgenograms of the chest and an electrocardiogram showed normal records. The results of the laboratory examinations are shown in Table II. The radial, ulnar, dorsalis pedis, and posterior tibial arteries are easily palpable.

The pre-operative studies on the peripheral circulation are illustrated in Figures 9 and 10. The vessels of the fingers are spastic and the plethysmographic records showed little or no pulsations. This was relieved by the application of local heat. The vessels are spastic at the time the effects of the median nerve block are being measured. Although block as produced with the characteristic numbness of the first three fingers of both hands, relief of the spasm did not occur. This is difficult to explain as there is only one other patient who has median nerve block failed to relieve functional spasm of the vessels of the first three fingers.

On April 20, 1938, Dr. Davis resected the stellate and third dorsal sympathetic ganglia from which the patient made an uneventful recovery. Measurements of the peripheral circulation were repeated after operation. The effects of local heat were measured on June 1, 1938, in similar procedures. The results, as shown by Figure 9, indicated the vessels are more spastic than before the operation. The Raynaud's symptoms had recurred. The effects of median nerve block were measured on October 5, 1938, and at this time (Fig. 10) as possible to obtain

following winter the symptoms were as severe, or more so, than before the operation. The symptoms continued to progress in severity and duration and crested ulcers beyond the first interphalangeal joints. In June, 1936, treatment for an old syphilis was started. Since that time she has had complete relief of the Raynaud's symptoms although ulcers still occur on the fingers. The scleroderma has improved.

Studies of the peripheral circulation were made in the fall of 1935. Figure 7 shows the effects of local heat on the peripheral pulse volume changes. The small response before and after heat indicates marked organic changes in the peripheral vessels,

especially in the left hand. Figure 8 shows the effects of median nerve block on the finger volume changes. This procedure produced an improvement of the circulation in fingers innervated by the median nerve. The operation should have destroyed the vasomotor fibers traveling in the median nerve. It is difficult to understand this result unless some vasomotor fibers still remained, or somatic motor fibers may be partly vasomotor in function. The patient does not perspire in the hands or arms. It does not seem likely, however, that regeneration of the vasomotor fibers would occur without regeneration of the sweat fibers.

This case is particularly instructive because it illustrates the inadequacy of our knowledge of the sympathetic nervous system as well as the pathogenesis of Raynaud's symptoms.

CASE 3. Bilateral removal of the stellate and third sympathetic ganglia.

D. L. White female, aged 49 years, was admitted to Passanant Hospital April 8, 1938, as patient of Dr. Lloyd Davis, for the surgical relief of Raynaud's symptoms. She complained that for the past 3 years her fingers had turned successively white, blue, dark red, then back to normal. Similar symptoms did not occur in the toes. These

attacks were brought on most easily by emotional spells, exposure of the hands to mild cold air, cool water, chills of the body and after she drank cold drinks and ate cold foods. There was numbness but no pain during these symptoms. The attacks could occur most frequently in the winter but some took place in the summer too. They were relieved by immersion of the hands in warm water. If this were not done, the attacks lasted until she overcame her emotional spell. The past history was negative except for attacks of migraine which began at the age of 6 years and continued until she was 45 years. The menopause occurred at the age of 45 years.

The physical examination was essentially negative. Roentgenograms of the chest and an electrocardiogram showed normal records. The results of the laboratory examinations are shown in Table II. The radials, ulnars, dorsalis pedis, and posterior tibial arteries were easily palpable.

The pre-operative studies on the peripheral circulation are illustrated in Figures 9 and 10. The vessels of the fingers were spastic and the plethysmographic records showed little or no pulsations. This was relieved by the application of local heat. The vessels were spastic at the time the effects of the median nerve block were being measured. Although block as produced with the characteristic numbness of the first three fingers of both hands, relief of the spasm did not occur. This is difficult to explain as there is only one other patient in whom median nerve block failed to relieve functional spasm of the vessels to the first three fingers.

On April 30, 1938, Dr. Davis resected the stellate and third dorsal sympathetic ganglia from which the patient made an uneventful recovery. Measurements of the peripheral circulation were repeated after operation. The effects of local heat were measured on June 1, 1938, by similar procedures. The results, as shown by Figure 9, indicated the vessels were more spastic than before the operation. The Raynaud's symptoms had recurred. The effects of median nerve block were measured on October 5, 1938, and at this time (Fig. 10) it was possible to obtain

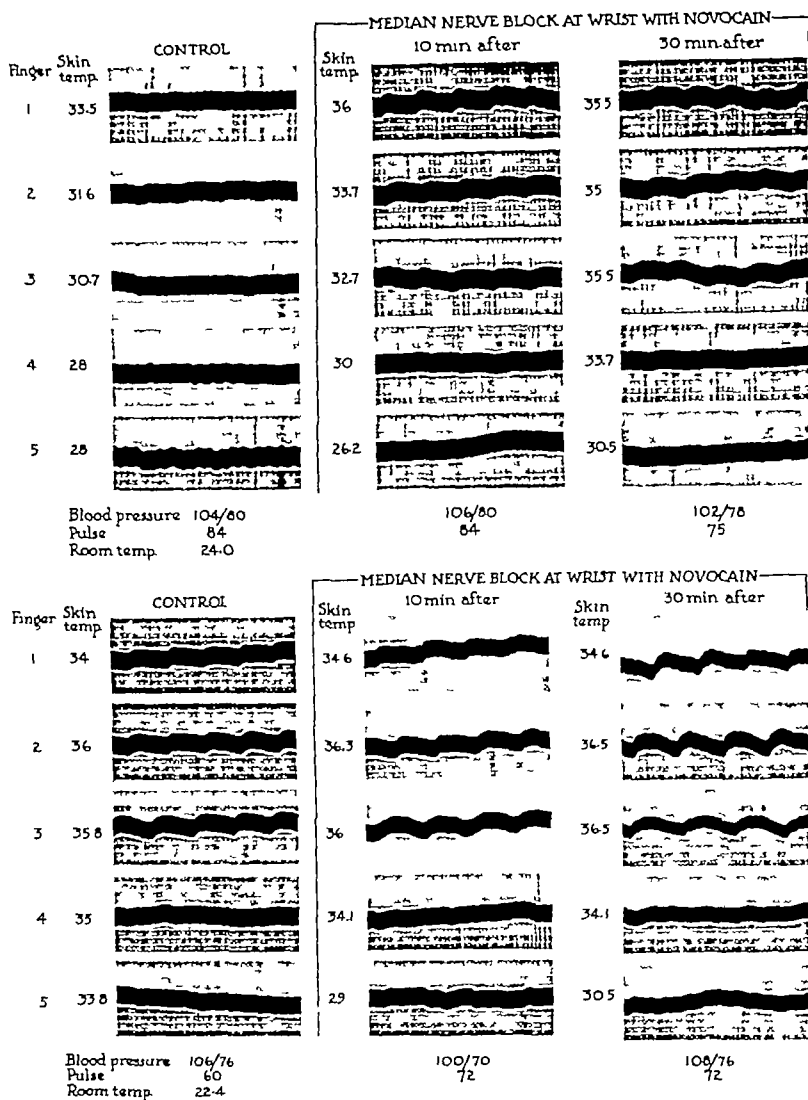

Fig 8 MB The effects of median nerve block on the finger volume changes, skin temperature of the fingers, pulse rate, and blood pressure. Note the moderate vasodilating effect of this procedure in the first 3 fingers of both hands as well as an increased skin temperature in these fingers. The finger volume changes of the fourth and fifth fingers did not change. In the fourth and fifth fingers of the right hand, below, the skin temperatures decreased, which is the usual finding in normal individuals from this procedure. Above, left hand record.

release of the vasospasm, even though theoretically, this should not occur following extensive surgery on the sympathetic nervous system. Three winters have elapsed since the operation. The Raynaud's symptoms are as severe as before the operation.

CASE 4 Bilateral pre ganglionic section of the sympathetic chain below the third dorsal ganglion.

Mr Y, white male, aged 47 years, was first seen on May 25, 1937, for Raynaud's symptoms. In 1932 he noticed

that all the fingers turned white to the metacarpal phalangeal joints, then passed through the various stages of blue, red, then normal. The symptoms had their onset in the toes also at the same time as in the fingers. They were brought on most easily by cool air, chilling of the body, or during emotional attacks, but were not affected by cold drinks. During the attacks he occasionally fainted. The Raynaud's symptoms lasted from a very short time to several hours, when nothing seemed to relieve them. The

Fig. 9. D.L. The effects of local heat to the hands on the finger volume changes before and 63 days following the bilateral removal of the stellate and third dorsal sympathetic ganglia. Note the absence of pulse volume changes in the controls both before above, and after below, the sympathectomy in spite of the increased skin temperature following the operation; the local heat produced about the same amount of oscillation before and after the operation.

attacks usually were relieved by immersion of the hands in warm water after shaking of the hands, or exercise. The condition was more in inter and comparatively absent during the summer.

1 February 1936, bilateral lumbar sympathectomy was done at the Hines Hospital by Dr. Da la. This changed the character but not the severity of the symptoms. The toes no longer turned white, but the stinging sensation in the toes persisted. The most distressing symptoms which occurred since the operation were profuse night sweats of the legs followed by sensation of extreme cold to the touch. The physical examination was essentially negative except for reference to the extremities.

The radial, ulnar, posterior tibial, and dorsalis pedis arteries palpated normally. Studies are made of the peripheral circulation (Figs. 2, 3, and 4). These results indicate there is no significant organic pathology in the peripheral vessels.

On June 1937 Dr. Da la did bilateral preganglionic section of the sympathetic chain below the third dorsal ganglia according to the method described by Gombosi.¹¹ Detailed postoperative studies of the peripheral circulation are made (Fig. 5). These results show that peripheral circulation had returned to pre-operative level in about 6 days. It is interesting to note that the sweating reaction in the arms and hands had returned in about 6 days.

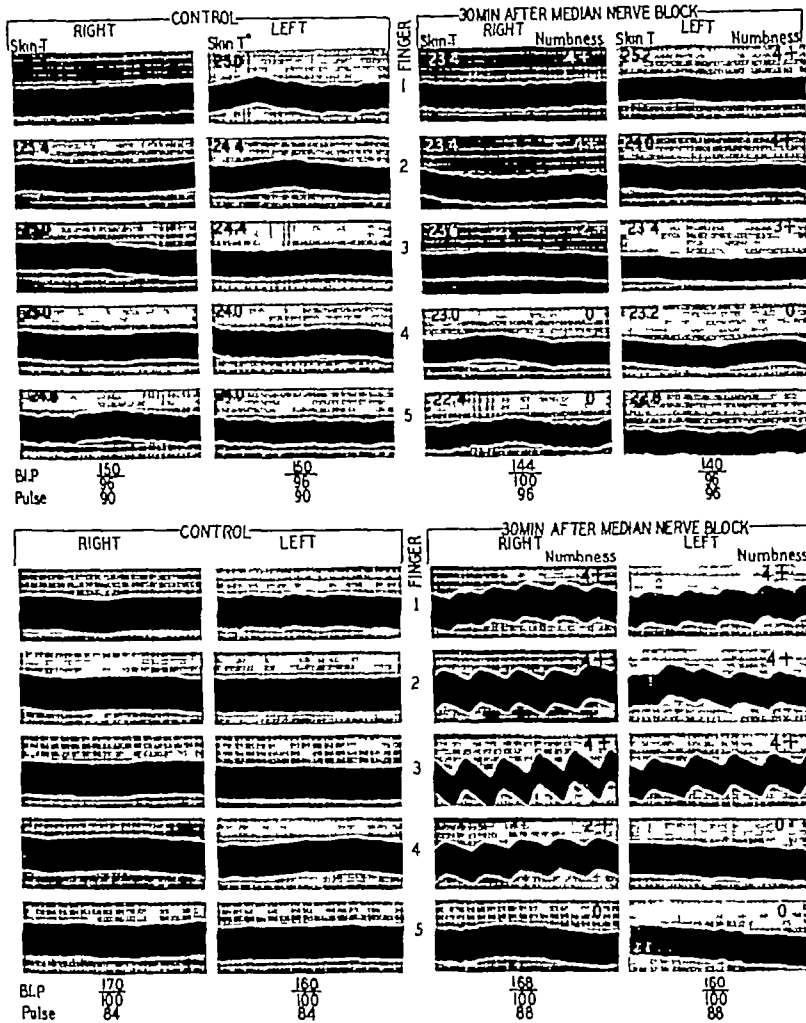

Fig 10 D L The effects of median nerve block with novocain at the wrist on the finger volume changes before, above, and below, 168 days following a bilateral removal of the stellate and third dorsal sympathetic ganglia Following the injection of novocain during the experiment as illustrated in the upper record, the patient felt faint and a severe attack of Raynaud's symptoms occurred in spite of a good nerve block as illustrated by the characteristic numbness in the first three fingers Note the absence of pulse volume changes in both the control and after median nerve block in the upper record, the low skin temperatures before and after nerve block which is not the normal response in the first three fingers The patient had typical Raynaud's symptoms during nerve block in the first three fingers of each hand In the lower record there is an absence of finger volume changes in the control records Following median nerve block, vasodilatation occurred in the fingers innervated by the median nerve, in the apparent absence of sympathetic vasomotor nerves The patient had a persistent absence of sweating in the upper extremities indicating the completeness of the operation The median nerve block induced a Raynaud's attack in the fifth fingers, apparently from diversion of blood to the other fingers

The effects of local heat were measured before and 12 days after operation, and of the median nerve block before and 14 days after operation (Figs 12 and 13) The results indicate that the peripheral vessels were able to dilate fol

lowing the operation just as before, indicating the circulation had returned to the pre-operative level Beneficial effects of the operation were only transitory for the symptoms recurred within 1 month and continued to be as severe

Fig. 3. The effects of the preganglionic type of sympathetic operation in which the sympathetic chain, as severed below the third thoracic on both sides. Note that there are no changes, vascular or otherwise, which persisted beyond the traumatic effects of the surgery.

or more so than before. He now has intractable headaches associated with the Raynaud symptoms and often faints. Last winter an attack of Raynaud symptoms lasted about 4 hours and could not be relieved by the usual methods.

It is interesting to note that his 6 year old son now has occasional attacks of Raynaud symptoms.

The results in this case indicate the inadequacy of surgical procedure for the relief of the patient's symptoms.

CASE 5. Removal of left stellate and second dorsal sympathetic ganglia and right preganglionic section of the sympathetic chain below the third dorsal ganglion.

H. H. White female, aged 36 years, as admitted to Painesant Hospital on the service of Dr. Loyal Davis for surgical relief of Raynaud symptoms. Her complaints are that all of her fingers turned white, then blue, red, and then finally normal. She had frequent headaches, dizziness, and congestion, and soreness in the eyes. The attacks of Raynaud symptoms began in her hands and feet at the same time about 8 years previously. She did not know whether the attacks were more in the hands or feet, but her attention was drawn mostly to her hands. Here the attacks were brought on most easily by exposure to cool air, less so by emotional spells, and less so by immersion of the hands in cold water. They were relieved most easily by exposure to warm air and water and would even stop spontaneously. The attacks necessitated staying indoors during the cold weather but could occur frequently in summer too.

No pain accompanied the attacks, but during the white stage the fingers felt cool and numb. Recovery with warm air left no further subjective symptoms. On the other hand, when the hands were placed in warm water produced sensation of pins and needles in the fingers.

Physical examination was essentially negative except that the hands appeared swollen. The peripheral vessels were easily palpable and pulsating. The results of laboratory studies are reported in detail in Table II. The abnormal findings are sedimentation rate 14, basal metabolic rate, -8 and mild secondary anemia.

Studies of the peripheral circulation by means of the digital plethysmograph showed that the effects of local heat and median nerve block before operation were moderate organic change in the peripheral vessels.

On July 22, 1935, the stellate and second dorsal sympathetic ganglia were removed on the left side while on the right preganglionic section was done according to the method of Smithwick.

Studies of the peripheral circulation were made daily following the operation until the circulation had reached its pre-operative level 8 days later (Fig. 4). The effects of local heat on the finger volume changes were measured 4 days after operation and were similar to the pre-operative records (Fig. 5). The effects of median nerve block also were measured 30 days after operation and, just as before the operation, the nerve block did not relieve the spasm in the fingers although the characteristic numbness occurred following the block. These results are similar to those of Case D. L.

ANALYSIS OF STUDY

The symptom complex now known as Raynaud's disease is very little understood in spite of the tremendous amount of study it has received since the original publications of Raynaud. The main reasons for this apparent lack of progress in our knowledge are (1) opinion differs as to whether Raynaud's disease exists as a clinical entity (2) the nature of the vascular changes are

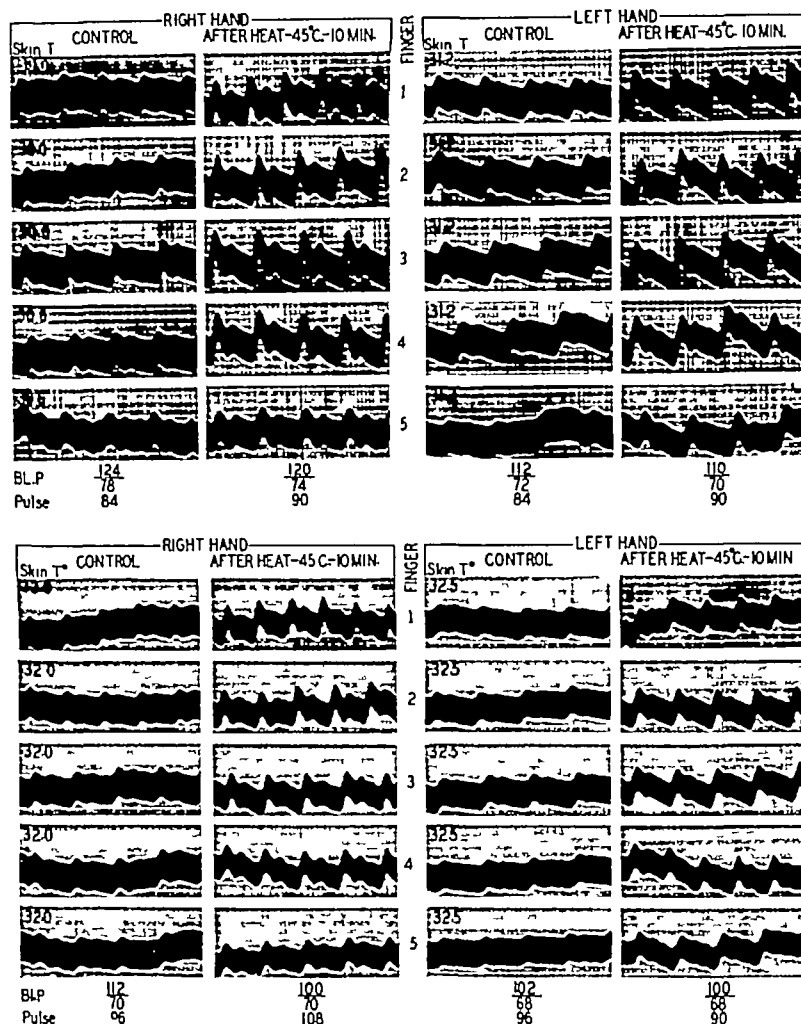

Fig 12 Y The records show the effects of local heat on the finger volume changes before, above, and, below, 12 days following the operation and one notes that about the same degree of vasodilatation is induced on both occasions

not understood, and (3) opinion differs regarding treatment. This discussion is based on a study of the 22 patients reported in this article.

A Does Raynaud's disease exist as a clinical entity? This answer is of fundamental importance, for it not only forms a common ground for the study of the symptom complex, but also would tend to rationalize understanding of the nature of the vascular changes, as well as the treatment of the symptom complex.

Hutchinson, more than 50 years ago, concluded that what is known as Raynaud's disease does not exist as a clinical entity and the peripheral mani-

festations observed are merely symptoms of some more fundamental disease. Hunt, in a more recent review of the subject, came to essentially the same conclusions and added that if Raynaud's disease exists at all, it must be very rare. He had no solution for a change in terminology. He believes that the term "Raynaud's disease" has such common usage it is doubtful it could be replaced by a more accurate descriptive term, such as Raynaud's syndrome.

The author arrives at the same conclusions from a study of the patients reported in this series, but is aware that persons examining these

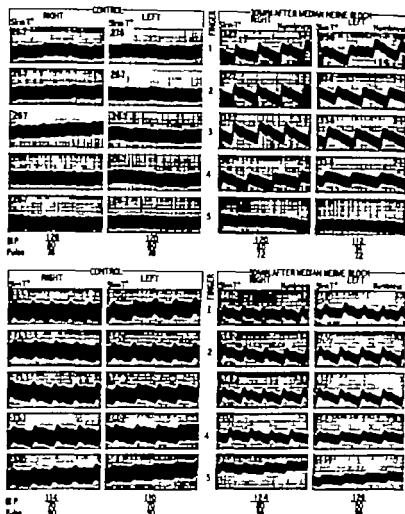

Fig. 3. A The effects of median nerve block 1 day before above, and 4 days after, below, operation mentioned in the legend under Figure. Note that it is possible to produce vasodilatation in the fingers innervated by the median nerve both before and after the surgery.

reports may doubt the accuracy of the diagnosis in many of the patients, as has occurred with Raynaud's original series. Certain data in these studies, however, throw light on the nature of the vascular changes during Raynaud's attacks and further bear out the opinion that the changes observed in the extremities of patients with Raynaud's attacks are merely symptoms of some more fundamental disease.

B The nature of the vascular changes in Raynaud's syndrome. The generally accepted view is that the blanching of the fingers or toes during Raynaud's attack is caused by an active peripheral

vascular constriction. The results of these studies indicate this may not be strictly so.

It is conceivable that the symptom complex in the fingers during a Raynaud's attack may be caused, in part, by a vasodilatation in the palmar arch and a passive collapse of the vessels in the fingers from an inadequate amount of the blood and blood pressure to keep them open. In other words, the blood may be shunted into the palmar arch without going through the fingers. The data in support of these ideas are as follows:

During a Raynaud's attack it has been widely observed that radial pulse does not change

Fig 14 H H The effects of a preganglionic type of operation on the right side and removal of the stellate and second dorsal sympathetic ganglia on the left side on the body temperature, skin temperature, blood pressure, pulse, and finger volume changes. Note that the finger volume changes returned to the pre operative level within 8 days, and that the skin temperature on the right side went below the control level while on the left it remained above the control level.

2 Blood can be diverted from the fingers in a normal individual by the administration of amyl nitrite, as shown in 1932 (3). A vasodilator drug which produces a vasodilatation in one place may produce a *passive* vasoconstriction in another if it causes sufficient diversion of blood to one area with a further resulting fall in blood pressure. In this particular case the amyl nitrite causes a diversion of the blood to the splanchnic area and a fall in blood pressure with insufficient blood and blood pressure to keep the finger vessels open. A similar phenomenon may exist in Raynaud's syndrome as a result of diversion of blood through the palmar arch.

3 One of the effects of median nerve block at the wrist and increased skin temperature is a vasodilatation in the first three fingers, less in the fourth finger, and a decrease in the fifth finger with a fall in skin temperature. The decrease in the circulation in the fifth finger from this procedure is caused by a diversion of blood to allow more blood to pass into the first three fingers. In patients with Raynaud's syndrome the same changes occur. A typical Raynaud's attack frequently occurs in the fifth finger alone. The most apparent explanation for this is that blood diverted from the fifth finger produces a Raynaud's attack, and not an active vascular constriction.

4 In patients with Raynaud's syndrome during periods of freedom from attack, measurements of the circulation of the fingers show a circulation less than normal even in the absence of any organic vascular changes. Under such circumstances it would seem logical to conclude that it would not require as much diversion of blood

to produce a Raynaud's attack as it would in a normal individual. The average amount of blood received by the five fingers under normal conditions is approximately 3.6 cubic centimeters of blood in one minute. In many patients with Raynaud's disease reported in this series, between attacks and under similar environmental conditions, the amount was far less, and measurements indicated that the amounts varied from less than 1 cubic centimeter per minute to the normal 3.6 cubic centimeters.

5 Patients with organic vascular changes who have Raynaud's syndrome suffer more distress from the attacks. It may be that even a lesser diversion of blood from the fingers can produce a Raynaud's attack.

6 If the lesser diversion of blood from the fingers can produce a Raynaud's attack, one cannot expect surgical removal of the vasoconstrictor fibers to the extremity to eliminate the attacks. This is shown by the poor results in 5 patients of this series.

7 Finally, there is so little direct evidence that the sympathetic nervous system is at fault in patients with Raynaud's syndrome, and considerable evidence that the humeral mechanism of peripheral vascular control may be impaired. Further study is indicated in this direction. The evidence of the importance of changes in the blood inducing Raynaud's attacks will be discussed in more detail under "The Treatment of Raynaud's Syndrome."

C The association of other diseases with Raynaud's syndrome. Other conditions or diseases are common with Raynaud's syndrome. In these

Fig. 5 H H L. The effects of local heat to the hands before, above, and so days following, below operation on sympathetic ganglia. Note the very low amplitude of the finger volume changes in the control records both before and after surgery and that finger volume changes are increased by the application of local heat in both cases.

series the following were found () secondary anemia—mild, 3 cases severe, 2 cases (3) syphilis, cases (3) organic vascular disease—peripheral vascular, 2 cases cardiovascular 3 cases (4) trophic disturbances—ulcers on fingers, 5 cases stiff finger joints, 5 cases loss of finger nails, 4 cases skin, scleroderma, 5 cases bones, sclerodactylia, 3 cases.

This common association with other diseases immediately presents two questions () How much does secondary anemia or syphilis contribute to Raynaud's symptoms? () Do the Raynaud's symptoms lead to organic vascular changes

and trophic disturbances or do they have a common etiology with these changes.

These questions can only partially be answered from observations of patients in this series. As to the first, the treatment of a mild or severe anemia resulted in improvement in all. The degree of improvement varied from slight to almost complete relief from attacks. Syphilis is occasionally associated with Raynaud's symptoms, and was present in 2 patients in this series. The effects of antiluetic treatment could not be observed in one of these patients because he did not stay under observation. In the other who also

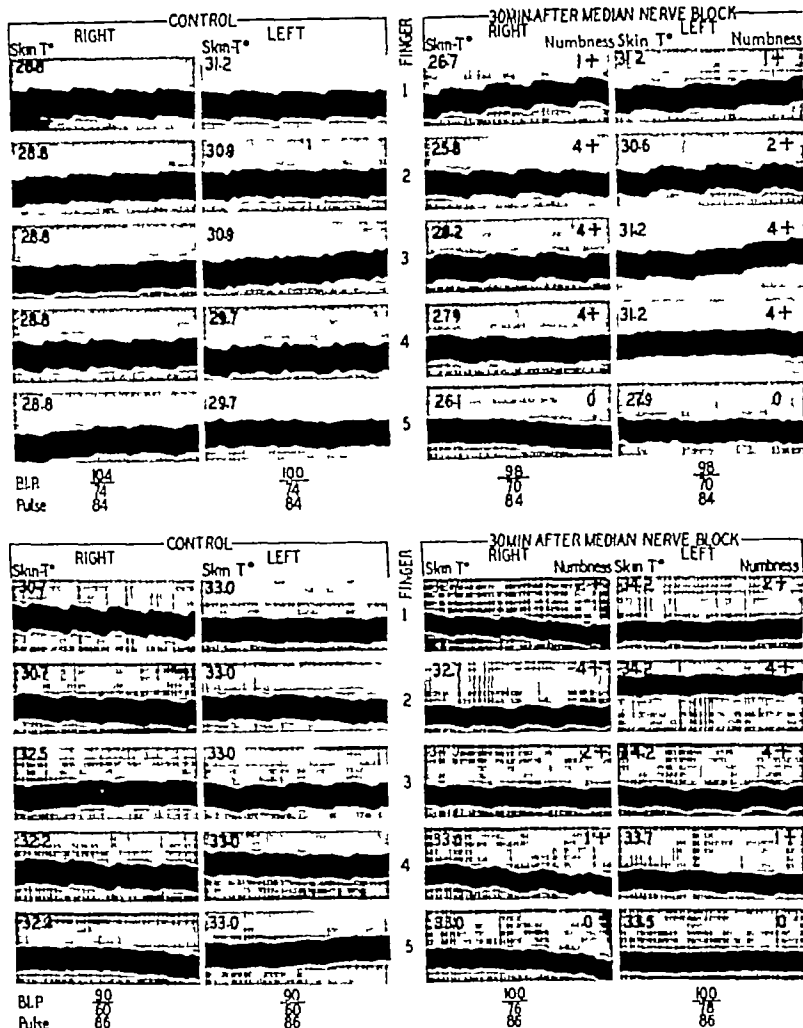

Fig 16 H H The effects of median nerve block at the wrist before, above, and below, 39 days following operation on the sympathetic ganglia. Note that the block did not produce the characteristic increase in finger volume changes in the fingers innervated by the median nerve, either before or after surgery, that the patient did experience the characteristic numbness in the fingers following the block, that the skin temperatures did not change appreciably, and showed no definite correlation with the finger volume changes and that injection of the median nerve induced a typical Raynaud's attack during the course of the experiment as illustrated by the upper record.

had scleroderma and sclerodactylia, complete relief from the Raynaud's symptoms and great improvement of the scleroderma followed anti-luetic treatment. Here a common etiology for the Raynaud's syndrome and the associated diseases is suggested. Organic vascular disease, present in a number of patients, varies from mild organic peripheral changes to severe cardiovascular disease with decompensation. One must

ask (1) How much of the organic changes are secondary to the Raynaud's symptoms? (2) Are the Raynaud's symptoms secondary to the organic vascular changes? (3) Do the Raynaud's symptoms and the organic vascular changes have a common etiology? The results of this study indicate they have a common etiology.

D The treatment of Raynaud's syndrome The treatment of Raynaud's syndrome varies with

circumstances as determined from each individual case but may follow certain broad principles, as follows:

1. No treatment necessary. In a group of patients (5 in this series) no definite etiology can be found, the symptoms are mild, and the Raynaud's syndrome shows no evidence of progression even after many years. Patient S. T. of this series illustrates this very well. She has been under observation for Raynaud's symptoms for 10 years. There has been no progress, the symptoms are very mild, and she has learned to avoid the attacks. In the meantime she has developed a cancer of the breast which is more distressing than the Raynaud's disease.

2. The treatment of associated diseases. It is very important to treat associated conditions or diseases, particularly secondary anemia and syphilis. The secondary anemia obviously involves the treatment of the cause of the anemia if it can be found.

3. Local treatment. This involves instructions to the patient to avoid the thing that brings on the attacks. Paraffin baths give considerable relief to some patients.

4. Surgery of the sympathetic nervous system. In 5 patients in the series, various types of surgery to the sympathetic nervous system were performed. No improvement was noted as judged over a period of years. Some reasons for this are in the next heading.

E. Notes on the early and late vascular effects of surgery to the sympathetic nervous system. These effects vary with the type of operation done as follows:

1. The effects of resection of the stellate and second or third dorsal sympathetic ganglia. Immediately following this type of operation there are present, (a) an increased skin temperature of the upper extremity, (b) cessation of sweating to the upper extremity, (c) an increased circulation in the fingers, and (d) a Horner's syndrome. Heat

dilatation in the course of the median nerve by nerve block at the wrist.

2. Following the so-called "preganglionic" sympathectomy to the upper extremity as done by White (1) the circulatory effects as well as any effects on heat regulation were transitory. It is doubtful that they lasted longer than the traumatic effects of the operation. Vasodilatation in the fingers could be produced following recovery from the surgery by local heat or median nerve block indicating the presence of nerves with vasomotor function.

It is difficult to reconcile many of the views expressed with some of those of the literature, especially those concerning treatment. One can say definitely that in this series of patients, medical management offered far more to the patient in the way of objective and subjective relief than surgery.

The importance cannot be overlooked of the recognition of patients with Raynaud's symptoms as part of some other disease as compared with the recognition of Raynaud's disease (which may not even exist as a clinical entity).

If Raynaud's disease exists as a clinical entity, it must be very rare. It is doubtful if any of the patients reported in this series had the disease. If this is true, the author never has seen a patient with unquestioned Raynaud's disease.

On the other hand 2 patients are reported with Raynaud's symptoms as part of some more fundamental disease. Medical management gave great deal of relief to a number of these patients. It would seem logical to conclude that it would be better to direct our attention to the recognition and treatment of Raynaud's symptoms as part of some other disease than to Raynaud's disease per se, which must be extremely

MUCINOUS CARCINOMA OF THE BREAST

OTTO SAPHIR, M.D. Chicago, Illinois

IT is often amazing to observe within an outspoken malignant epithelial tumor glandular or cystic structures filled with a basophilic homogeneous material in which perhaps only a few groups of carcinoma cells are still recognizable. From adjacent structures having adenocarcinomatous portions one gains the impression that perhaps this evidently secreted material has led to an atrophy and the eventual destruction of the tumor cells. In other words, the mucin which originally had been secreted by the tumor cells had subsequently caused their disappearance. Apparently because of the intriguing assumption of a seeming self-destruction of cancer cells, this type of carcinoma was early recognized as a separate variety of carcinoma, especially in the breast. As early as 1852 investigators classified this cancer of the breast as an especially benign form principally because of the conception of the destruction of the tumor cells by their own secretions.

Though this carcinoma early was recognized as a special type until recently relatively few studies have been undertaken of mucinous carcinoma of the breast. The more recent interest in this entity may perhaps be traced to the studies of Cheate and Cutler who showed that mucinous degeneration in breast carcinomas is more common than is generally supposed and emphasized that the presence of gelatinous degeneration in these tumors does not necessarily imply a low degree of malignancy as was generally supposed.

The nomenclature of these tumors is confusing. The terms colloid, gelatinous, mucoid, mucinous, and myxomatous are used indiscriminately. It seems that since mucin is the product of epithelial cells the only correct term to designate these tumors is mucinous, because these tumors are epithelial in nature and evidence of secretion is often noticeable in the individual tumor cells. Kärner emphasized the correctness of the term mucinous carcinoma. Furthermore, the staining reaction is more characteristic of mucin. According to Kärner the term colloid is used because of the brown color and gelatinous consistency. Colloid should be reserved for tumors of the thyroid gland and hypophysis which secrete

colloid. Mucoid, meaning resembling mucin, does not occur in epithelial tumors but is seen particularly commonly in connective tissue tumors. Gelatinous is purely a descriptive term referring to the similarity of the material to gelatin, but does not denote a specific substance. Yet Ewing, contrary to this, stated that true mucin is found chiefly in connective tissue tumors, pseudomucin in epithelial growth. From the foregoing it is clear that the more correct term for these tumors is mucinous carcinoma, which nomenclature will be strictly adhered to.

An opportunity presented itself to study several instances of mucinous carcinoma. Surgical specimens and autopsy material from patients who had died from this carcinoma were available. Particularly because of the latter and because it was soon realized that what was thought to constitute one group of tumors in reality consisted of several types of carcinomas, it was thought of interest to report the results of this study.

A complete review of this subject does not seem necessary. Geschickter recently reviewed in detail the available data. It may be of interest, however to mention that as early as 1852 and 1853 Lebert, Larrey and Robinson had studied mucinous carcinomas and stressed the slow growth of these cancers. Later curiously enough, the interest in these tumors culminated in the purely theoretical question as to whether the mucinous, or as it was called—colloid material, took its origin from the epithelial cells or from the connective tissue framework. Even among the earlier investigators there were a few who doubted the entirely benign course of these breast carcinomas. Gaabe, 1908, remarked that occasionally the mucinous carcinoma may lose its mucinous characteristics, its cells may take on a high degree of anaplasia and the tumor may revert to a carcinoma of the usual type. But Shepherd, 1938 still emphasized that gelatinous carcinoma of the breast is of low malignancy and is easily cured by radical excision but if recurrence takes place, the prognosis is bad because of the insistence of the growth.

Cheate and Cutler 1931 reported 10 instances of mucinous carcinoma of the breast. They remarked upon the prevailing opinion that this is the least malignant form of a mammary carcinoma, that metastases occur late, and that the

prognosis is more favorable. They specifically mentioned that with few exceptions the conception that this form of cancer may be highly malignant is not encountered in the literature. Five of their 10 tumors were among the most malignant, they stated, that can be encountered in the breast. Morphologically they were highly anaplastic and clinically their high degree of malignancy was demonstrated by prompt recurrence, widespread metastases, and rapid course. Lee, Hauser, and Pack, 1934, stressed the rarity of mucinous carcinoma of the breast. These investigators classified this carcinoma into (a) primary mucinous carcinoma in which the mucinous features predominate, (b) ordinary carcinoma with secondary mucinous degeneration. In these latter instances the mucinous degeneration may be recognized histologically only, whereas other portions may be highly malignant. The latter group again is subdivided into "myxoid carcinoma" in which the mucinous changes arise by metaplasia in the connective tissue whereby the latter becomes "myxomatous," and into "mucoid carcinoma,"

Fig 2 True mucinous carcinoma. Note the islands of tumor cells not exhibiting evidence of anaplasia, or mitotic figures. Iron hematoxylin preparation $\times 155$

a variety in which the mucinous material originates directly from the carcinoma cells. It must be mentioned that this classification is made on presumptive evidence, since the authors did not offer evidence for the dual origin of the mucinous material. However, they refer to the observation of Ewing who described compact alveoli lying in broad areas of a mucous stroma with no evidence of mucous degeneration of the epithelium, as supporting the connective tissue origin of the mucinous changes. These authors also mentioned a mucinous type of tumor which has the structure of a papillary carcinoma.

Geschickter, 1938, classified these mammary cancers into two groups. In one, the tumors con-

tain a shiny translucent gel throughout their substance and in the second group the gelatinous change is found in one or more portions, and solid, dense tissue in the remainder of the growth. It seems that Geschickter's classification is almost identical with that of Cheate and Cutler and also with that of Lee, Hauser and Pack. Among those cancers in which the mucinous changes predominate Geschickter however further mentioned a type which contains epithelium of the basal cell variety. Judging from the relatively benign character of the epithelium and from the large amount of mucinous substance he believed that the prognosis is unusually good.

Gillespie and Schmeisser 1939, also stressed the rarity of these tumors. They described 3 instances of mucinous carcinoma of the breast in

which the mucinous changes were part of a medullary and of a duct carcinoma, respectively. They stressed the presence of mucinous material in adenocarcinomas of the breast, in intracystic papillary carcinoma duct, and scirrhous carcinomas.

Ewing 1941 stated that, as a rule when mucous degeneration overtakes a tumor while a rapid increase in size may follow the tumor has reached the acme of its cellular activity and its malignancy is reduced. He stressed that mucoid carcinoma is a relatively benign form of cancer.

It may be mentioned in this connection that there have also been observed in our laboratory a number of carcinomas of the breast in which the connective tissue stroma was spread by an edema-like material, sometimes resembling mu-

cin These changes obviously involving the connective tissue stroma, not related to the carcinoma, do not form part of this study. These are merely mentioned here because of Ewing's statement that there are evidently two types of gelatinous carcinoma, one in which the mucinous changes have involved and partly originated in the fat tissue and stroma, and one in which the alveoli are filled with mucus.

This study is based on the postmortem examination of 2 patients who had died from widespread mucinous carcinoma of the breast, and on the examination of 7 breasts which had been removed for cancer which on histological examination also proved to be mucinous in character. In some instances sections of the whole breast or large portions of the breast were cut according to Cheate's method. In other instances serial sections of the tumors and surrounding structures were made. The sections were stained with Delafield's hematoxylin and eosin or with Weigert's iron hematoxylin. Elastic stains (orcein) and the van Gieson stain were employed when deemed necessary. Also the mucicarmine stain for the presence of mucin was used.

It is not intended to give detailed clinical histories, and only essentials which seem important will be mentioned in connection with the pathological lesions encountered.

After all tumors had been examined, it seemed clear that the term "mucinous carcinoma" was rather broad and that undoubtedly various types of so called mucinous carcinoma existed. These tumors have been grouped and will be discussed accordingly.

True mucinous carcinoma. Of this type only one instance was observed.¹ Here large mucinous areas which apparently formed the bulk of the tumor were encountered. The outstanding gross changes were large, circumscribed, pale yellow areas which were of semifluctuant consistency and which were separated from one another by thin strands of fibrous tissue. Histologically most of the fields consisted of a pale bluish staining material often encased by a thin membrane, apparently the wall of a cyst. Hardly any cellular elements were seen and only occasionally epithelial cells with vesicular nuclei and basophilic cytoplasm were encountered, singly or clustered in small groups without any particular arrangement. As Lee, Hauser, and Pack expressed it, the cells were often "isolated in a sea of mucus." These cells showed no evidence of anaplasia and mitotic figures were rarely encountered. The lymph nodes were not involved. The patient was about

50 years of age. A radical breast resection was performed and the patient is in perfect health 7 years after the operation.

This tumor corresponds in every detail to the original description of mucinous carcinoma, and there seems to be no need of a more detailed description. This is the type which led to the conception of the benignity of these tumors. It very likely is an adenocarcinoma arising from the acini of the breast. The outstanding histological findings are the presence of the mucinous material with very few cellular elements and the absence of other malignant epithelial structures.

Mucinous carcinomatous features in duct carcinoma. This is perhaps the most common type of so called mucinous carcinoma and most of the reported tumors fall into this group. At least 7 of the 10 tumors reported by Cheate and Cutler come under this classification. Of the 7 tumors removed surgically in this series, 5 must be designated as duct carcinoma with mucinous features.

Grossly these tumors may or may not be characteristic of mucinous carcinomas, though 4 of these 5 showed large, yellowish, semifluctuant regions similar to those seen in true mucinous carcinomas. But often, adjacent to these regions or sometimes in the middle of obviously mucinous areas, were firmer, grayish-pink, seemingly well circumscribed portions of tumor revealing bright yellow streaks. The extent of these two portions of which the tumor consisted varied considerably. The histological sections showed a mixture of typical duct carcinomatous structures and mucinous carcinoma. Large tumor cells with varying amounts of cytoplasm often filled small or larger ducts. Atypical mitotic figures were common and anaplasia was marked. Often groups of these cells were observed, more or less isolated and infiltrating the surrounding breast structures. In addition many cysts and dilated ducts were encountered, filled with a lightly stained basophilic material in which were groups of cells or isolated cells. These cells showed characteristics similar to those just described. Often, however, the nuclei were absent and mitotic figures were rarely encountered. Often within the cyst and within the mucinous material there were outlines of, or even well preserved, minute vessels and capillaries, though the tumor cells which must have been there before could not be made out. Sometimes the walls of these minute vessels were broken and many red blood corpuscles were seen within the cysts. It is of interest that in one of these tumors an intracystic papilloma and in another an intracystic papillary carcinoma were also present. It should be stressed here that the latter is met with not

¹I am indebted to Dr. Paul Klemperer for this tumor.

tain a shiny, translucent gel throughout their substance and in the second group the gelatinous change is found in one or more portions, and solid dense tissue in the remainder of the growth. It seems that Geschickter's classification is almost identical with that of Cheate and Cutler and also with that of Lee, Hauser and Pack. Among those cancers in which the mucinous changes predominate Geschickter however further mentioned a type which contains epithelium of the basal cell variety. Judging from the relatively benign character of the epithelium and from the large amount of mucinous substance, he believed that the prognosis is unusually good.

Gillespie and Schmetzner 1939 also stressed the rarity of these tumors. They described 3 instances of mucinous carcinoma of the breast in

which the mucinous changes were part of a medullary and of a duct carcinoma, respectively. They stressed the presence of mucinous material in adenocarcinomas of the breast, in intracystic papillary carcinoma, duct, and scirrhous carcinoma.

Ewing, 1940 stated that as a rule when mucous degeneration overtakes a tumor while a rapid increase in size may follow the tumor has reached the acme of its cellular activity and its malignancy is reduced. He stressed that mucous carcinoma is a relatively benign form of cancer.

It may be mentioned in this connection that there have also been observed in our laboratory a number of carcinomas of the breast in which the connective tissue stroma was spread by an edema-like material sometimes resembling mucus.

velvety, broadly attached tumor which consisted of a large number of well circumscribed, small or minute excrescences. These were covered and separated from one another by mucinous material. Histologically the tumor consisted of round, oval and, more often, spindle shaped epithelial cells resembling transitional cells of the urinary tract, and an insignificant, thin, connective tissue stalk. These cells were covered by a mucinous material and much of this was also present between groups of these cells. The wall of the cyst was well preserved. Because of the spindle shaped cells the tumor could be classified as a transitional type of intracystic papilloma (Saphir and Parker). Geschickter apparently drew attention to this type of tumor, to which he referred as gelatinous carcinoma containing epithelium of the basal cell type. He stated that judging from the relatively benign character of the epithelium and from the large amount of mucoid substance, the prognosis in these growths should be unusually good.

EVALUATION

It has been shown that the tumors classed as mucinous carcinoma of the breast are not one entity but apparently consist of various forms of tumors of the breast, four of which have been described. The true mucinous carcinoma, originally described as colloid or gelatiniform carcinoma is said to be of low grade malignancy. Only if sections through the whole breast or serial sections show no other types of malignant structures, may such a tumor be designated as true mucinous carcinoma. This form, however, seems the rarest. Not a single such instance was observed in this laboratory among over 700 cancers of the breast, the tumor described here having been received from another laboratory. Because of the insufficient material little can be said as to the origin of this type of cancer. It is probable that this tumor arises from the acini. This is apparent because of the histological finding of many small acini and the absence of duct structures which are so common in other forms of mucinous carcinoma of the breast. It is interesting to note that Geschickter described three tumors which microscopically are indistinguishable from basal cell cancer of the adenocystic type, such as is found in the parotid gland. A portion of the growth actually may resemble benign mixed tumors of the parotid gland. He believed that typical mucoid cancer of the mammary gland may originate as a form of adenocystic basal cell cancer. It seems quite possible that these tumors may be very early forms of true mucinous carcinomas of the breast. Perhaps the adenocystic structures described by Geschick-

ter may constitute acini of the breast filled with mucin. The similarity of these early tumors to the adenocystic basal cell carcinoma is interesting because of the comparative benignity of these tumors and of the true mucinous carcinomas of the breast.

As mentioned before, the duct carcinoma of the breast with mucinous features is undoubtedly the most frequently encountered type of so called mucinous carcinoma. It seems that the mucinous changes are purely secondary, the underlying tumor being a duct carcinoma. In contradistinction to the third form, this variety shows the secreted mucin outside the tumor cells. The tumor cells are apparently soon destroyed and signet cells are not found. It is obvious that the degree of malignancy does not depend upon the presence or the amount of mucin but upon the unchanged duct carcinomatous structures.

Intracystic papilloma or intracystic papillary carcinoma are often found in these tumors, not only in this series but often in the tumors described in the literature. Though this finding offers some interesting speculation in regard to a possible relation of duct carcinoma and mucinous changes, to intracystic papilloma, this and other studies have not disclosed any relationship. It seems most likely that the simultaneous occurrence of these lesions is purely coincidental.

The signet ring cell variety is perhaps the most interesting and the two autopsy findings recall Cheate and Cutler's statement that some of the mucinous carcinomas are among the most malignant tumors encountered in the breast. The widespread metastases in both autopsied cases, the rapid recurrence in the first, and the fact that when the second patient was seen, operation was too late because of the widespread metastases, indicates the high malignancy of these tumors. In both patients the ovaries were involved and studded with signet shaped tumor cells. It must be emphasized, of course, that in neither of the patients was a primary malignant tumor encountered in the gastro-intestinal tract, though metastatic tumors were found in the wall of the small intestine in the second patient. This suggests, perhaps, a peculiar affinity of these signet shaped tumor cells for the ovaries as seen in carcinoma of the stomach with signet ring cells—metastases to the ovaries (Krukenberg's tumor). On the other hand, however, it is interesting to note that one patient whose breast was radically removed for eradication of such a tumor is apparently well, four years postoperatively.

This variety of mucinous carcinoma is also found in combinations with duct carcinoma

rarely in outspoken duct carcinomas. The former probably is a coincidental finding and might not have been discovered had not the entire breast been examined.

As mentioned previously "mucinous features" in duct carcinomas constitute the most common form of so called mucinous carcinoma. In these tumors the presence of mucin is apparently incidental and the tumor follows, as a rule, the course of a duct carcinoma. These tumors apparently belong to those mucinous carcinomas concerning which Ewing remarked that they may prove highly malignant. This he explained by the distention of tissue spaces by the mucus which distention supposedly facilitates the dissemination of the surviving cells.

Signet ring cell mucinous carcinoma. This type of carcinoma consists predominantly of secreting tumor cells. So much secretion is retained within the cells that they assume signet ring shapes. Three such tumors were encountered. One of these was a surgical specimen and the 2 others were found at postmortem examination. The surgically removed tumor was found beneath the nipple and consisted of a rather firm, ill defined mass measuring 4 centimeters in greatest dimension. The nipple was not fixed. On section the tumor was grayish-white but showed a few yellowish glistening and bulging areas. In the remainder of the breast foci of fibrosis and cysts were recognized. With the exception of these glistening areas there was nothing noted from which the mucinous character of the tumor might have been inferred. Histologically the tumor consisted mainly of well circumscribed foci of epithelial cells which showed either a lightly stained basophilic cytoplasm with nuclei situated at the base of the cells which often assumed the typical signet ring forms. Often the cytoplasm in the sections seemed clear only the cell membranes and the crescent shaped nuclei being recognizable. In other fields small or larger cystic structures could be noted filled with a basophilic material and relatively few epithelial cells. However instead of clumps of epithelial cells with clear cut, round nuclei and basophilic cytoplasm as seen in the true mucinous carcinomas, the cells suspended in the cystic structures here were signet shaped and had clear cytoplasm. These cells were also often seen isolated from ducts or acini, in the stroma. Serial sections of the breast, however, also showed ducts which were crowded with tumor cells which either were typical of duct carcinoma cells with many anaplastic cells and numerous atypical mitotic figures or showed transition to signet ring cells as described. Some fields showed duct carci-

nomatous structures and adjoining these accumulations of signet ring cells. Metastases to the axillary lymph nodes consisted only of the signet shaped tumor cells. The patient, a 55 year old white female, had noted the tumor only a short time before consulting the physician. A radical mastectomy was performed, not followed by radiation treatment and the patient, after 4 years, is apparently well.

A similar tumor was found in the 2 patients who came to autopsy. In the first instance, a 35 year old white female, a radical breast amputation had been performed 4 months before death. The autopsy revealed a local recurrence and metastases to the sternum, mediastinal lymph nodes, peritoneum, inguinal lymph nodes, liver and both ovaries. As a matter of fact, both ovaries were so markedly enlarged—measuring about 12 centimeters in greatest dimension—that at first they were thought to be the seat of primary solid tumors. The tumors histologically consisted principally of slightly basophilic cells with flattened, crescent shaped nuclei. When the previously removed breast tumor was examined, sometime later it proved to be histologically a duct carcinoma with transitions to the mucin secreting signet shaped cells just described. In the second autopsy the tumor was found in the left breast of a 49 year old colored female. It measured 4 by 5 by 5 centimeters in greatest dimensions, was of a rather firm consistency but was not noticed by the patient until shortly before she entered the hospital, where she died before treatment could be instituted. The autopsy revealed metastases in the axillary lymph nodes, pleura, lungs, pericardium, peritoneum, intestinal wall, retroperitoneal lymph nodes, suprarenal glands, ovaries, and spinal column. Histologically the breast tumor consisted mainly of signet ring cells either arranged in groups or singly invading the surrounding stroma. However serial sections also revealed outspoken duct carcinomatous structures. The metastases, however, consisted only of the signet ring cells.

Intracystic papilloma with mucinous features. Only one such tumor was observed. This was found in a 47 year old woman who had a small tumor in the left breast which suddenly became enlarged, at which time a hemorrhagic discharge from the nipple was noted. Grossly the tumor consisted of a cyst measuring about 4 centimeters in greatest dimension, which was filled with a hemorrhagic and mucinous material in which small, yellowish pieces of soft, granular tissue were found loosely intermingled. The inner wall of the cyst presented a rather soft and friable,

velvety, broadly attached tumor which consisted of a large number of well circumscribed, small or minute excrescences. These were covered and separated from one another by mucinous material. Histologically the tumor consisted of round, oval and, more often, spindle shaped epithelial cells resembling transitional cells of the urinary tract, and an insignificant, thin, connective tissue stalk. These cells were covered by a mucinous material and much of this was also present between groups of these cells. The wall of the cyst was well preserved. Because of the spindle shaped cells the tumor could be classified as a transitional type of intracystic papilloma (Saphir and Parker). Geschickter apparently drew attention to this type of tumor, to which he referred as gelatinous carcinoma containing epithelium of the basal cell type. He stated that judging from the relatively benign character of the epithelium and from the large amount of mucoid substance, the prognosis in these growths should be unusually good.

EVALUATION

It has been shown that the tumors classed as mucinous carcinoma of the breast are not one entity but apparently consist of various forms of tumors of the breast, four of which have been described. The true mucinous carcinoma, originally described as colloid or gelatiniform carcinoma is said to be of low grade malignancy. Only if sections through the whole breast or serial sections show no other types of malignant structures, may such a tumor be designated as true mucinous carcinoma. This form, however, seems the rarest. Not a single such instance was observed in this laboratory among over 700 cancers of the breast, the tumor described here having been received from another laboratory. Because of the insufficient material little can be said as to the origin of this type of cancer. It is probable that this tumor arises from the acini. This is apparent because of the histological finding of many small acini and the absence of duct structures which are so common in other forms of mucinous carcinoma of the breast. It is interesting to note that Geschickter described three tumors which microscopically are indistinguishable from basal cell cancer of the adenocystic type, such as is found in the parotid gland. A portion of the growth actually may resemble benign mixed tumors of the parotid gland. He believed that typical mucoid cancer of the mammary gland may originate as a form of adenocystic basal cell cancer. It seems quite possible that these tumors may be very early forms of true mucinous carcinomas of the breast. Perhaps the adenocystic structures described by Geschick-

ter may constitute acini of the breast filled with mucin. The similarity of these early tumors to the adenocystic basal cell carcinoma is interesting because of the comparative benignity of these tumors and of the true mucinous carcinomas of the breast.

As mentioned before, the duct carcinoma of the breast with mucinous features is undoubtedly the most frequently encountered type of so called mucinous carcinoma. It seems that the mucinous changes are purely secondary, the underlying tumor being a duct carcinoma. In contradistinction to the third form, this variety shows the secreted mucin outside the tumor cells. The tumor cells are apparently soon destroyed and signet cells are not found. It is obvious that the degree of malignancy does not depend upon the presence or the amount of mucin but upon the unchanged duct carcinomatous structures.

Intracystic papilloma or intracystic papillary carcinoma are often found in these tumors, not only in this series but often in the tumors described in the literature. Though this finding offers some interesting speculation in regard to a possible relation of duct carcinoma and mucinous changes, to intracystic papilloma, this and other studies have not disclosed any relationship. It seems most likely that the simultaneous occurrence of these lesions is purely coincidental.

The signet ring cell variety is perhaps the most interesting and the two autopsy findings recall Cheate and Cutler's statement that some of the mucinous carcinomas are among the most malignant tumors encountered in the breast. The widespread metastases in both autopsied cases, the rapid recurrence in the first, and the fact that when the second patient was seen, operation was too late because of the widespread metastases, indicates the high malignancy of these tumors. In both patients the ovaries were involved and studded with signet shaped tumor cells. It must be emphasized, of course, that in neither of the patients was a primary malignant tumor encountered in the gastro-intestinal tract, though metastatic tumors were found in the wall of the small intestine in the second patient. This suggests, perhaps, a peculiar affinity of these signet shaped tumor cells for the ovaries as seen in carcinoma of the stomach with signet ring cells—metastases to the ovaries (Krukenberg's tumor). On the other hand, however, it is interesting to note that one patient whose breast was radically removed for eradication of such a tumor is apparently well, four years postoperatively.

This variety of mucinous carcinoma is also found in combinations with duct carcinoma.

However whereas in the signet cell variety the individual secreting tumor cells remain intact, but lose their connections with the duct structures, invade diffusely the surrounding breast and produce widespread metastases, in the second variety here described, the secreting tumor cells are apparently destroyed and only the duct carcinoma cells are responsible for the behavior of the tumor. It may be mentioned in this connection that Gillespie and Schmeisser described in one of their three tumors scattered epithelial elements separated by a loose stroma filled with mucin. There were solid nests of cells or definite gland formations. Some of the cells contained transparent droplets. Others were distended with mucinous material which pushed the nuclei aside, causing a signet ring appearance.

The intracystic papilloma with mucinous features is apparently not a malignant tumor but probably behaves as the transitional cell papilloma (Saphir and Parker). The benignity of these tumors was indicated by Geschickter who stated that 19 of his 25 patients showing this tumor were traced. With the exception of 3 dying from other causes, all survived the 5 year period.

SUMMARY

This study reveals that mucinous carcinoma of the breast is not a single entity but can be classified into at least four definite types of tumors. The *true mucinous carcinoma* consists of duct or cystic structures filled with mucinous material in which groups of or isolated, tumor cells may still be recognizable here and there. There are no other tumor structures present. This is apparently a rare tumor which clinically is relatively benign. The original conception of the benignity of these tumors must be traced to this variety of mucinous carcinoma of the breast. The *duct carcinoma with mucinous features* is the most common type. Areas similar to those seen in true mucinous carcinoma are intermingled with duct carcinomatous structures. Sometimes, however, these latter portions are seen only after sections of the whole breast have been examined. These tumors are just as malignant as simple duct car-

cinomas. The *signet ring cell mucinous carcinoma* is characterized histologically by well preserved mucin secreting cells with basophilic or clear cytoplasm and crescent shaped, compressed nuclei situated at the base of the cells. Whereas in the two former groups the secreting cells are soon destroyed, disappear and large spaces filled with mucin remain, in the third group the signet ring tumor cells remain intact. Soon they become isolated from ducts and acini, invade the stroma and may produce the most widespread metastases, particularly in the ovaries. Though duct carcinomatous structures may also be present in this variety the metastases consist mostly of signet ring shaped cancer cells. This tumor is regarded as highly malignant. Two patients died from widespread metastases soon after the detection of the primary tumor. Yet one patient is alive 4 years after operation. The fourth variety may be designated as *intracystic papilloma with mucinous features*. This is a relatively rare, nonmalignant tumor.

THE ACCURACY OF ROENTGEN ESTIMATES OF PELVIC AND FETAL DIAMETERS

A LOUIS DIPPEL, M D , F A C S , and E DELFS, M D , Baltimore, Maryland

MODERN roentgen pelvimetry and fetometry have been extensively developed during the past 6 years. As a result, they have been utilized by many hospitals and teaching institutions, in some, routinely in every primigravida and in every multipara with a previous history of difficult labor or delivery, and in others, only in selected cases, such cases being chosen for roentgen study after careful external and internal clinical mensuration and palpation. There are still, however, many obstetricians who do not utilize this valuable clinical aid. In some localities the number of definitely contracted pelvis is relatively so small that roentgen pelvimetry is not often necessary and, under these circumstances, no urgent need is felt for the information obtained from roentgen pelvimetry and fetometry. Furthermore, there are many obstetricians who have not been convinced of the precision of these roentgen procedures. It cannot be said that these clinicians refuse to be convinced, but rather that those of us working in the field of obstetrical roentgenography have not placed sufficient importance upon the precision of our various techniques and have not emphasized the range of probable error in each. The main purpose of this paper is to attempt to evaluate the precision of several commonly employed roentgen methods of pelvimetry and fetometry.

The simplest technique, and the one most universally utilized in this country today, is the position method devised and perfected by Thoms (18-21), and modified by Torpin. Walton's method may be included here, since it depends upon essentially the same principles. The accuracy of the pelvic estimations from the inlet view, by these methods, is dependent solely upon the ability of the clinician or the x-ray technician to locate the plane of the pelvic inlet from external bony landmarks. As early as 1789, Baudelocque contended that the plane of the inlet lay in the plane located by the upper border of the symphysis pubis, anteriorly, and the depression beneath the spine of the fifth lumbar vertebra, posteriorly. It soon became evident to both anatomists and

obstetricians that this was rarely the case, and roentgenologists have repeatedly shown that the posterior external landmark lies at a much lower level than the sacral promontory or even the projection of the iliopectineal lines on the sacrum. Accordingly, Thoms (21) has elevated the posterior external landmark until at present his technician marks the depression beneath the spine of the third lumbar vertebra. Torpin uses as the posterior endpoint the space lying between the spinous processes of the fourth and the fifth lumbar vertebrae.

It must not be forgotten that there is considerable individual variation in pelvis and that often the plane of the pelvic inlet will not be located precisely from even these currently employed bony landmarks. However, Thoms (21) says that his "experiments with dried pelvises have shown us that this posterior point may vary as much as 2.5 centimeters above or below the ideal situation, without measurably affecting the mensuration as recorded on the film." Since he measures to the nearest one-quarter of a centimeter on the film, it follows that his maximum error should be ± 2.5 millimeters, provided the anterior external landmark is correctly located and the posterior one is selected not more than 2.5 centimeters above or below the ideal location. The error under these circumstances can be mathematically proved to be not in excess of ± 2.1 per cent. The only means of determining the correctness by which these external landmarks are located is to observe the selected ones on the lateral film. Thoms (21) suggests that this lateral film could be taken first and developed before selecting the ideal location for the posterior external landmark. This should remove all doubt concerning the precision of the estimates made of the pelvis from its inlet view. Our own experience with the use of lead shot over the external landmarks, in 25 cases, has shown that such a step is necessary if the plane of the pelvic inlet is to be closely enough approximated by the plane of the external landmarks to keep the error consistently below 5 per cent. However, apparently without this precautionary step, Schumann measured the anteroposterior and transverse diameters of the pelvic inlet in a group of women,

From the Department of Obstetrics, Johns Hopkins University and Hospital.

tance of the object below the x-ray tube (166 88 cm)

From similar triangles

$$\frac{AB}{a b} = \frac{TH}{TF}$$

$$\text{or, } \frac{10}{a b} = \frac{166.88}{182.88}$$

$$\text{solving, } 166.88 ab = 182.88 \text{ cm}$$

$$ab = 10.96 \text{ cm}$$

But, 10 cm = 100% of actual length of the object,
and, 10.96 cm = 109.6% of actual length of the object,
or 0.96 cm. = 9.6% of actual length of the object

Therefore, 9.6 per cent represents the amount of triangular distortion of a pelvic diameter in a lateral teleoroentgenogram. Thus it is seen that pelvic or fetal estimates from teleoroentgenograms are overestimated by essentially 10 per cent under normal pelvic conditions. Any haphazard position method, or even a rough guess at the object-film distance, would produce more accurate results. Moreover, much bony detail is sacrificed in reducing the amount of triangular distortion by increasing the tube-film distance.

All stereoscopic methods may be considered together, for they differ only in the instruments employed in working up the material. These methods have the advantage over the position methods that they require no positioning of the patient other than to show the pelvic diameters to best advantage, and their accuracy is not based upon the correct localization of external bony landmarks, nevertheless there are steps in procuring these roentgenograms which require precision. For instance, it is necessary to employ register or centering markers, so that when these, in each pair of stereoscopic films, are accurately superimposed, the result obtained is exactly the same as though both exposures had been made on a single negative. This can be accomplished with relative ease by adding permanent or removable markers to the cassette carrier. Another equally important precaution is to employ the precise tube-film and tube-shift distances which are called for by the particular technique being used. Failure to observe the latter rule is probably the most common cause of technical errors in stereoscopic pelvimetry.

The ideal means of avoiding such errors would be the construction of a precise x-ray machine, such as the one in Hodges' (10) laboratory, for not only have the tube-film and tube-shift distances been precisely calibrated, but they can not be altered. If the technician then utilizes the total available tube-shift distances, there can be no question that these films are precise and estimations from them should be as nearly 100 per cent accurate as human error in interpreting them will allow. Unfortunately, no other x-ray laboratory

Fig. 1. Diagram indicating the distortion resulting from teleoroentgenography.

has produced a similar precision x-ray machine and all other investigators have continued to utilize more or less non-precise x-ray machines. As a result, practically all these others have inserted into each pair of stereoscopic films, a radio-opaque marker of known length. The position of this marker is immaterial, the only requirement being that it appear in each film and that its position remain unchanged until both of a pair of stereoscopic films have been obtained. The chief point of interest lies in the attitude of various investigators toward this known marker.

Clifford (6, 7) measures the control markers in each pair of films and says that if the method has been executed properly, the maximum error should be 0.2 centimeter, in other words, the maximum technical error should be ± 2.0 per cent, for the control markers are actually 10 centimeters long. In those instances in which the technical error is greater, it has been customary at the Boston Lyng-In Hospital to repeat the procedure, or to indicate that the results are not extremely reliable. Clifford reports an accuracy of within 3 millimeters in 97 per cent of the Class A films, i.e., those in which there has been no fetal head movement between or during the stereoscopic exposures. Since the classification of his films depends upon the presence or absence of evidence of fetal head movement, the accuracy of estimates of the pelvic diameters should be equally as good as the figures given, provided the endpoints are clearly visualized, for movement of the maternal pelvis between, or during, exposures is rare.

Johnson (13, 14) inserts a marker of known length into his stereoscopic films, but apparently does not measure its images routinely with his stereoroentgenometer. Since the basic principle

both at laparotomy, and from a roentgen inlet view made by Thoms technique and they came to the conclusion that the variation in length of each diameter, as determined by the two means, was constantly less than 2.0 millimeters.

The extent of error in the anteroposterior pelvic diameters, as determined from the Thoms lateral roentgenogram should amount only to that due to human error in applying a caliper length to a distorted centimeter scale, plus the probable error due to poor visualization of the endpoints of those diameters. This latter becomes a definite entity to be reckoned with when we deal with diameters extending to or from the lower margin of the symphysis pubis; the same is true of the ischial tuberosities, which, even with very good roentgen technique, are often not clearly outlined on the roentgenogram. Nevertheless, with accurate placing of the lead ruler and the production of a true lateral view of the pelvis, the precision by this method should reach a very high degree of accuracy in symmetrical pelvis, for the intergluteal fold in all such cases probably lies in the sagittal plane of the pelvis. The same can be said of the lateral roentgenogram which is being developed by Hodges (12) and in which one-half the bitrochanteric diameter is used as the object-film distance.

The accuracy of roentgen cephalometry by the position methods mentioned leaves much to be desired. The precise determination of the distance between the geographical center of the fetal head, or between the endpoints of any fetal diameter and the film, is the great source of error. Walton, however, has devised a unique method of checking the accuracy of his object-film distances. Lead markers are fixed to the anterior and to one lateral wall of the abdomen, over what is believed to be the geographical center of the fetal head, in each anteroposterior and lateral view. Both anteroposterior and lateral roentgenograms are taken without shifting the position of the patient from the supine. If the image of the radio-opaque marker appears at or near the geographical center of the fetal head, the previously recorded object-film distance can be used and accurate estimations of fetal head diameters anticipated.

Ball's method (-3) has gained considerable popularity during the past few years and affords the minimum of mathematical manipulation. His present cephalometer (3) consists of a nomographic chart with a movable indicating member which carries the calculations from the raw data immediately to the estimate of the length of the pelvic or fetal head diameter with one step

The estimation by the Ball method, of the object-film distance of any pelvic or fetal head diameter appearing, for instance, in the lateral view is made from bony landmarks appearing in the anteroposterior view and includes the use of certain empiricisms. Thus, the object-film distance for the obstetrical conjugate diameter is estimated by measuring, on the anteroposterior film, the distance between the symphysis pubis and a point on the greater trochanter to which must be added the table top to film distance. The point on the greater trochanter is a variable one and depends upon the tube-film distance used, being more laterally placed with greater tube-film distances. Ball believes that the distance between the point on the greater trochanter and the lateral surface of the thigh represents the amount of triangular distortion in the lateral film. He (3) has compared one-half the bitrochanteric diameter as measured upon the patient, with the diameter obtained from bony landmarks, and has found that these correspond so closely that he believes arbitrary bony landmarks sufficiently accurate for practical purposes. However in an earlier communication, he says that the pelvic diameters are considered to be accurate to within 5 mm. The mean circumference of the fetal head is accurate to within 1 cm. in the majority of cases and 2 cm. in all cases." In a more recent article (2) he concludes that in general it may be said that there has been a maximum error of 10 per cent in fetal head volume and 5 per cent in linear diameter measurements.

From time to time, since Varnier's work, in 1900, one investigator or another has rediscovered the idea that there is less distortion of an object when roentgenographed at a tube-film distance of 6 feet than at the more commonly employed tube-film distances, and has proposed that roentgenograms with the former technique represent undistorted radiography. Buchner has recently utilized this procedure in obstetrics, but we discuss the method only to indicate the relatively large radiographic distortion in teleroentgenograms, and to show that they are neither accurate nor record prenatal findings without bias. This can best be shown by similar triangles, as follows (Fig. 1)

Let FF represent the film, T the x-ray tube, AB a pelvic diameter which for convenience we assume measures 10 centimeters and HF an object-film distance of 16 centimeters, i.e., one-half the normal bitrochanteric diameter. The ab represents the projection of AB on FF when roentgenographed from a tube-film distance, TF of 6 feet (182.88 cm.) and TH represents the dis-

tance of the object below the x-ray tube (166.88 cm)

From similar triangles

$$\frac{AB}{10} = \frac{ab}{166.88} \quad \frac{TH}{10} = \frac{TR}{166.88}$$

or,

$$\text{solving, } 166.88 \cdot ab = 182.88 \text{ cm}$$

$$ab = 10.96 \text{ cm}$$

But, 10 cm = 100% of actual length of the object,
and, 10.96 cm = 109.6% of actual length of the object,
or 0.96 cm = 9.6% of actual length of the object.

Therefore, 9.6 per cent represents the amount of triangular distortion of a pelvic diameter in a lateral teleoroentgenogram. Thus it is seen that pelvic or fetal estimates from teleoroentgenograms are overestimated by essentially 10 per cent under normal pelvic conditions. Any haphazard position method, or even a rough guess at the object-film distance, would produce more accurate results. Moreover, much bony detail is sacrificed in reducing the amount of triangular distortion by increasing the tube-film distance.

All stereoscopic methods may be considered together, for they differ only in the instruments employed in working up the material. These methods have the advantage over the position methods that they require no positioning of the patient other than to show the pelvic diameters to best advantage, and their accuracy is not based upon the correct localization of external bony landmarks, nevertheless there are steps in procuring these roentgenograms which require precision. For instance, it is necessary to employ register or centering markers, so that when these, in each pair of stereoscopic films, are accurately superimposed, the result obtained is exactly the same as though both exposures had been made on a single negative. This can be accomplished with relative ease by adding permanent or removable markers to the cassette carrier. Another equally important precaution is to employ the precise tube-film and tube-shift distances which are called for by the particular technique being used. Failure to observe the latter rule is probably the most common cause of technical errors in stereoscopic pelvimetry.

The ideal means of avoiding such errors would be the construction of a precise x-ray machine, such as the one in Hodges' (10) laboratory, for not only have the tube-film and tube-shift distances been precisely calibrated, but they can not be altered. If the technician then utilizes the total available tube-shift distances, there can be no question that these films are precise and estimations from them should be as nearly 100 per cent accurate as human error in interpreting them will allow. Unfortunately, no other x-ray laboratory

Fig. 1. Diagram indicating the distortion resulting from teleoroentgenography.

has produced a similar precision x-ray machine and all other investigators have continued to utilize more or less non-precise x-ray machines. As a result, practically all these others have inserted into each pair of stereoscopic films, a radio-opaque marker of known length. The position of this marker is immaterial, the only requirement being that it appear in each film and that its position remain unchanged until both of a pair of stereoscopic films have been obtained. The chief point of interest lies in the attitude of various investigators toward this known marker.

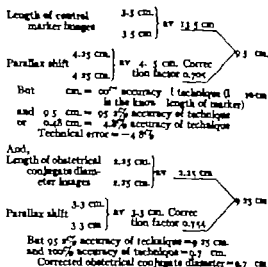

Clifford (6, 7) measures the control markers in each pair of films and says that if the method has been executed properly, the maximum error should be 0.2 centimeter, in other words, the maximum technical error should be ± 2.0 per cent, for the control markers are actually 10 centimeters long. In those instances in which the technical error is greater, it has been customary at the Boston Lying-In Hospital to repeat the procedure, or to indicate that the results are not extremely reliable. Clifford reports an accuracy of within 3 millimeters in 97 per cent of the Class A films, i.e., those in which there has been no fetal head movement between or during the stereoscopic exposures. Since the classification of his films depends upon the presence or absence of evidence of fetal head movement, the accuracy of estimates of the pelvic diameters should be equally as good as the figures given, provided the endpoints are clearly visualized, for movement of the maternal pelvis between, or during, exposures is rare.

Johnson (13, 14) inserts a marker of known length into his stereoscopic films, but apparently does not measure its images routinely with his stereoroentgenometer. Since the basic principle

of stereoradiometry is sound, he does not consider it to be of great importance to establish the accuracy of his particular stereoscopic x ray machine.

Although Caldwell and his co-workers are primarily interested in pelvic morphology we find in the Moloy precision stereoscope (15, 16) not only a recognition of technical error but also the first utilization of it. After inserting their anteroposterior films into the precision stereoscope and before measuring the pelvic diameters with it, Moloy and Swenson (16) first measure the projected image of the known marker. If this measurement does not coincide with the known length of the marker, they alter the position of the optical system of the stereoscope and remeasure the image of the known marker. This procedure is continued until the measured length of the marker image coincides with its known length. By this procedure, the projected image of the pelvis should of necessity duplicate precisely the actual size of the pelvis. No statement on the accuracy of their estimates of pelvic diameters is made, since the accuracy is entirely dependent upon the experience of the observer with their stereoscope and upon his original stereoscopic sense.

During the development of the technique for the roentgen pelvimetry and fetometry studies at the Johns Hopkins Hospital, we realized the need of control markers of known length and some accounting of the technical errors, for the available x ray machine was not precise. In each pair of stereoscopic films, the estimated length of the known marker was calculated by the graphic method of Hodges (10, 11). The deviation of this estimate above or below the known length of the marker was considered a positive or a negative technical error and its magnitude expressed in terms of percentage of the known length of the marker. At the same time, we were measuring the obstetrical conjugate diameter of the pelvis at the time of each laparotomy on the service. We noted, as was to be expected, that the smaller the roentgen technical error the more closely the roentgen estimate of the diameter approached its actual length, as measured at operation. We then reasoned that we had been estimating the nature and the magnitude of the technical error from the marker of known length and that we should be able to correct all our original estimates of pelvic diameters to the extent of this technical error and produce estimates of the pelvic diameters which were of essentially 100 per cent accuracy. The following was the course of procedure:

This procedure resulted in the corrected roentgen figure approaching the actual length of the pelvic diameter somewhat more closely than the uncorrected figure, but the corrected figure and the actual length of the pelvic diameter never coincided exactly. However, this procedure made it possible for us to report in an earlier paper (8) an average roentgen accuracy in measuring the obstetrical conjugate diameter of ± 1.6 millimeters in 25 patients. Moreover the technical error in each of these was never in excess of ± 5 per cent. A further study of such comparative figures showed that negative technical errors resulted in overestimates of the pelvic diameters and positive technical errors in underestimates, the extent of the overestimate or underestimate depending upon the magnitude of the technical error.

The following mathematical procedures show a means of calculating the precise length of a pelvic diameter from the pair of stereoscopic films used for the mathematical calculations given, i.e., films produced by a non-precision x ray machine and showing a definite technical error.

True length known marker = its image length F (a correction factor)

Substituting available data $10 = 3.5 F$
and, solving, $F = 0.74$, i.e., this correction factor applied to the image length of the known marker will give the true length of that marker cm.

Now $F = \frac{K}{P + K}$ where K = tube shift distance and P = measured parallax shift

Substituting, $74 = \frac{K}{4.35 + K}$

Solving, $K = \text{cm.}$ 1 is obtaining the above pair of films total tube-shift of 2.1 cm. was used

instead of 10 16 cm We assume that essentially the correct tube-film distance, 91.44 cm, was used, since it is more easily measured with precision on the x-ray machine than the tube shift distance and since errors in tube film distance do not produce as great technical errors as do errors in tube shift distance.

Then, solving for the true length of the obstetrical conjugate

$$\text{as above, } F = \frac{K}{P + K}$$

$$\text{Substituting, } F = \frac{12.1}{3.3 + 12.1}$$

Solving, $F = 0.786$ (correction factor for the obstetrical conjugate images obtained from the actually employed roentgen technique)

Furthermore

$$\begin{aligned} \text{True length of obstetrical conjugate} &= \text{its image length} \times F \\ &= 12.25 \times 0.786 \\ &= 9.62 \end{aligned}$$

This obstetrical conjugate actually measured 9.6 cm at laparotomy and this estimate is much more precise than the uncorrected roentgen figure, even more precise than the corrected estimate for it

Thus, it is seen that it is possible to obtain precise estimations of pelvic diameters by this means of utilizing the marker of known length and from its images calculating the actual tube-shift distance used by a non-precision x-ray machine. The overestimate of the pelvic diameter from a use of the magnitude and nature of the technical error was not great. However, longer diameters at greater object-film distances have been found to result in errors amounting to more than 6.0 millimeters when calculated by the use of the technical error. This is true since the curve for triangular distortion correction factors is not a straight line, and this fact also explains why the use of the technical error method of correction does not result in precise estimations of pelvic or fetal diameters. If the curve were in reality a straight line, the latter procedure would be mathematically sound.

By comparing the estimate of a pelvic diameter obtained by the precision method described (i.e., by calculating from the known marker images, the actual tube-shift distance employed and then determining the correction factor for this tube-shift and the tube-film distance) with the uncorrected and corrected estimates of the same diameter as obtained by the application of the technical error, we have noted a strikingly close approximation of the average of these last two estimates to the former. These approximations are shown in the appended table. It is, therefore, shown that the shorter mathematical procedure represented by the use of the technical error method can be used and will produce re-

markably precise estimates of pelvic and fetal diameters.

An immediate objection to the last described methods will be that they entail considerable mathematical manipulation. This is, of course, true, but such mathematics is usually simple arithmetic, never more complicated than high school algebra. Furthermore, if we expect to attain precision, it will probably not be accomplished through great simplicity. We do not propose that it should be necessary to go through a lengthy mathematical procedure routinely for every available pelvic or fetal diameter, in every pair of stereoscopic films. What we do wish to emphasize, however, is the need for determining the technical error in every pair of stereoscopic roentgenograms obtained by a non-precision x-ray machine and the utilization of this error, when it is a sizable one, in cases of borderline pelvic contraction. Only in such a manner will it be possible to furnish precise estimates of maternal pelvic or fetal diameters in cases in which precision will definitely indicate a choice between spontaneous delivery or a more radical elective procedure.

Recently, Friedman and Euphrat have published a preliminary report of a parallax method based upon principles originally described by Hodges and Ledoux (10). The results obtained with this method were highly accurate in measuring a dried pelvis. They have demonstrated that some mathematical manipulation may be avoided and extremely accurate pelvic estimates obtained by simply locating the footpoints of the target from its respective stereoscopic positions and utilizing these. It would seem that this should be a relatively simple and highly accurate method for diameters which are parallel to the film, provided the footpoints can be accurately located. This latter task may necessitate some calibration of the x-ray machine, if precision is to be consistently obtained. Moreover, the calculation of diameters which are not parallel to the film will require additional but simple mathematical procedure, as well as some precise knowledge of tube-film and tube-shift distances. However, this method offers valuable possibilities for the accurate determination of most of the important obstetrical diameters from stereoscopic films which are produced by the average roentgen-ray equipment.

During the past 5 years, we have primarily employed the Hodges graphic method, with the modifications described, to obtain more precise end-results than were otherwise possible with the nonprecision x-ray machine at our disposal. During the past year, we have occasionally resorted

Fig. 2. Photograph of precision caliper used in measuring pelvic diameter at the time of laparotomy. It is made of two cylinders, one telescoping into the other on screw and is calibrated in one-tenths of a millimeter. The surface of one end is slightly curved, so that it will fit snugly on the sacral promontory when measuring the obstetrical conjugate. The curved plate on the outer cylinder is for purposes of grasping and holding the instrument between the fingers of one hand while the other hand is used to screw the inner cylinder in or out until the instrument fits snugly between the endpoints of the pelvic diameter.

to the precision method for the calculation of extremely important pelvic diameters in cases of cephalopelvic disproportion or markedly contracted pelvis. Also, in search of simpler yet precise technical and mathematical methods, we have tried several other methods in current use in this country. Finally a series of patients were measured by these several methods and certain actual pelvic measurements obtained with a precise caliper (Fig. 2) at laparotomy; museum specimens of bony pelvis were similarly studied. Table I shows a few comparative estimates and measurements of obstetrical conjugate diameter.

It has been our experience that the technical difficulties with mensuration of pelvic diameters at laparotomy are great, in spite of the use of a precision instrument and even on a diameter with as definite endpoints as the obstetrical conjugate. In our opinion, it is for this reason that roentgen estimates of a pelvic diameter more closely approach the actual measurement on a museum specimen of a pelvis than on the living subject at laparotomy.

In Table I the Hodges graphic method indicates our own modifications of his original method. We consider the average figures from this method to be the most precise from any method we have thus far used with a nonprecise x ray machine, except possibly for the precision method. We have continued to use the former since pelvic diameters may be estimated from a previously calculated table of triangular distortion correction factors, thus eliminating the necessity for calculating the correction factor for each diameter to be estimated. Our stereorontgenometer is of the Hodges (11) type and furnishes highly accurate estimates when the technical error is small. However when these errors are large, we can not expect a high degree of accuracy for the stereorontgenometer. It is set for the roentgen technique supposed to have been employed in obtaining the stereoscopic films. Yet, as is shown in the table, the end-results are quite accurate when we utilize the technical error method of correction, as in the case of the graphic method and obtain the average between corrected and uncorrected estimates. Furthermore, as will be seen in the table, the corrected figures are over estimates to almost exactly the same degree as the uncorrected figures are underestimates, quite irrespective of the method of mensuration of the nonprecise stereoscopic films. The footpoint method is essentially the same as that described by Friedman and Euphrat, except that the target footpoints were located by means of a simple device developed in Hodges' laboratory and is a method which requires no precise knowledge of the x ray factors employed in obtaining the stereoscopic films except for the tube-film distance. Further precise information is of course, necessary in this method only when the pelvic diameter to be measured lies at an angle to the film.

TABLE I—ESTIMATES OF THE LENGTH OF THE OBSTETRICAL CONJUGATE

Subject of study	Methods employed, with resultant estimates and direct measurements of obstetrical conjugate								
	Hodges graphic			Precision	Stereorontgenometer			Footpoint	Direct measurement
	Uncorrected	Corrected	Average		Uncorrected	Corrected	Average		
Pelvis A			46	45	65	19.17	96	90	60
Pelvis B	8	96	5	47	80	19	45	19.96	—
Patient L. J.	89		13.90	90	85	95	94	17.00	11.45
Patient I. R.	10	75	90.90	61	30.65		10	30.90	30.91
Patient Z. M.		30.86	30.86	49	10.30	10.30	30	25	29.70
Patient T. W.	40		51	51	30	95		30	45

*Obtained from several roentgen methods compared with the direct measurement obtained from two museum specimens of bony pelvis and from our patients at the time of laparotomy.

The end-results obtained by this method are generally quite accurate and with further experience, such inaccuracies as shown under patient L J, can be avoided. An error was anticipated in this case, since the footpoints fell very near to the longitudinal plane of the pelvis. As a rule, the estimates from the "Thoms lateral" view were quite accurate. Our errors with this method have undoubtedly resulted from not placing the lead ruler in the median plane of the pelvis. Such errors were usually avoided by the "Hodges lateral" method (not shown in the table), in which one-half the clinical bitrochanteric measurement is used as the object-film distance. However, it is true that both of these latter two methods will produce errors in certain asymmetrical pelvises.

Results from lateral pelvimetry alone have been recorded here, although quite similar results were obtained in these subjects from anteroposterior pelvimetry. The true endpoints of the greatest transverse diameter of the inlet are more difficult to make out, both on roentgenograms and at operation, than those of the obstetrical conjugate in the lateral view, and hence transverse measurements do not lend themselves as readily to comparisons. However, good results were obtained with the Hodges graphic, precision, and stereoroentgenometer methods, when used as for the lateral view. The accuracy of the footpoint method varied somewhat, aside from the occasional incorrect lateral placement of the target footpoints. The results with the Thoms inlet view varied directly with the precision by which the posterior external endpoint of the pelvic inlet could be located.

SUMMARY

1 A plea is made for concrete evidence by each investigator of the accuracy of roentgen estimates of pelvic and fetal diameters, as compared with easily measurable diameters on museum specimens or obstetrical patients at laparotomy. General knowledge of their accuracy should increase the utilization of such valuable prenatal aids as roentgen pelvimetry and cephalometry.

2 Each of the popular methods of obstetrical roentgen mensuration has an accuracy which is generally adequate for clinical purposes.

3 Two mathematical procedures for the production of precise estimates from stereoscopic films taken by a nonprecision x-ray machine, are given.

4 In our hands, the Hodges graphic, the precision, and the stereoroentgenometric methods

have proved almost equally good in the production of precise estimates of maternal pelvic and fetal diameters. The footpoint method has shown variations in precision but has very definite possibilities. The Thoms and the Hodges lateral methods for measurement of anteroposterior pelvic diameters are generally quite accurate, but correct placement of the lead ruler in the former is highly essential to precision, and pelvic asymmetry precludes consistent precision with either method. The Thoms inlet view has furnished us with precise estimates of transverse pelvic diameters only when we have been fortunate in approximating the level of the pelvic inlet in the selection of the posterior external bony landmark.

We acknowledge with gratitude our indebtedness to Dr Paul C Hodges for valuable aid and suggestions throughout our studies in obstetrical roentgenography. The close co-operation of the Division of Roentgenology of the Johns Hopkins Hospital, and especially that of Mr James C Fletcher, its chief technician, has made it possible for us to employ several roentgen techniques and to prove the accuracy of each.

CONSTRUCTIVE OCCLUSION OF THE SUPERIOR VENA CAVA

Report of Three Cases in Which the Patients Were Treated Surgically

HOWARD K. GRAY, M.D., F.A.C.S., and IRA C. SKINNER, M.D., Rochester, Minnesota

CONSTRUCTIVE occlusion of the superior vena cava with or without accompanying thrombosis of the vessel is fortunately a very rare occurrence. Ochsner and Dixon, in 1936, after an exhaustive study of the world literature, were able to collect only 120 cases of thrombosis of the superior vena cava. Erlich, Ballou, and Graham, in 1934, found only 309 cases of all types of obstruction to the superior vena cava. Hinshaw and Rutledge have recently added to this list 20 cases in which the patients were examined personally by them at the Mayo Clinic. The causation of the occlusion in 4 of their cases was thought to be constriction of the vessel, with associated thrombosis resulting from inflammatory changes in the mediastinum.

The collected cases of thrombosis of the superior vena cava have been classified by Ochsner and Dixon as to causation in the following manner: 44, 36.6 per cent, resulted from phlebitis; 35, 29.1 per cent, from external compression; 28, 23.3 per cent, from mediastinitis; and in 13, 10.8 per cent, the cause either was not stated or was unknown. Of the 44 cases of phlebitis and associated thrombosis, 20 were classified as idiopathic, 10 were associated with cardiac disease, 12 were cases of syphilitic phlebitis, 4 were tuberculous phlebitis, 7 were pyogenic phlebitis and 1 was traumatic phlebitis. External compression was thought to be the cause of thrombosis in 35 cases. Of these 35, 18 were associated with mediastinal neoplasms and the remainder with aneurysms. Of the 28 cases in which there was antecedent mediastinitis, syphilis was the etiological agent in 11 cases, tuberculosis in 10 cases, trauma in 1 case, and in 5 the causation of the mediastinitis was unknown. The underlying etiological agents named in order of their frequency in the production of thrombosis of the superior vena cava in the reported cases are: syphilis, tuberculosis, cardiac disease, pyogenic infections, and trauma.

The average age of the patients in the reported cases was 43.6 years. The disease occurred approximately twice as frequently among male patients as among female patients.

From the Division of Surgery, the Mayo Clinic and the Department of Surgery, the Mayo Foundation.

As a result of occlusion of the superior vena cava, a marked increase in the venous pressure in the upper half of the body occurs, with the production of a characteristic clinical picture. Edema of the face, neck, and upper extremities becomes a distressing feature. At the onset of the condition the edema may be intermittent. It decreases after the patient has been up and around and is aggravated by the recumbent position. Exercise and bending forward on the part of the patient exaggerate the edema. Edema of the eyelids may be an early sign of the disease. Sudden death has been attributed to edema of the glottis by Rauth. Cyanosis, particularly of the lips and lobes of the ears, may be a prominent feature. Suffusion of the conjunctival vessels and dilatation of the retinal veins on funduscopic examination are again evidence of venous stasis. Dyspnea, occurring as a result of chemical changes in the blood, is present early. Stasis in the cerebral vessels results in congestion of the cerebrum and increased pressure of the cerebrospinal fluid. Headache may be the presenting symptom. In one of our patients typical jacksonian epilepsy developed, as occurred also in the case reported by Chiray and Semelaigne. In Samek's case, psychosis developed. Other symptoms, such as vertigo, somnolence, deafness, tinnitus, epistaxis and visceral disturbances, have been reported. Pleural effusion may occur. Occlusion of the superior vena cava manifests itself objectively in increased venous pressure, collateral diversion of the blood stream, and delayed circulation time. Fischer has divided obstructions into three anatomical types together with the number of times each type occurred: (1) obstruction below the orifice of the azygos veins, 31 of 166 cases; (2) obstruction including the azygos veins, 121 of 166 cases; (3) obstruction above the orifice of the azygos veins, 14 of 166 cases. Carlson (3) demonstrated experimentally in dogs that obstruction of the superior vena cava above the azygos veins was well tolerated, whereas obstruction below those veins was fatal for the 2 animals in which it was attempted. Occlusion of the azygos system and superior vena cava could be successfully accomplished if carried out in two stages. Carlson found that an early return to relatively normal

associated with neoplasia, the rate was 94.4 per cent and in 24 cases those in which mediastinitis was present, 22 patients died. Of the 44 patients who had phlebitis, 32 died. In addition to this terrific mortality it is probable that those patients who survived were incapacitated for long periods. As is evident, the prognosis is dependent to a large degree on the etiological agent causing the thrombosis. Until relatively recently, there has been very little in the way of treatment to offer these unfortunate people. Phlebotomy with removal of several hundred cubic centimeters of blood may be temporarily beneficial. Antisyphilitic therapy is of great value for those patients who have syphilitic endophlebitis or mediastinitis. Roentgen therapy is of no benefit unless an associated radiosensitive tumor is present. Skillern, in 1917, made the suggestion that decompression of the thorax might be of some benefit in those cases in which there was increased intrathoracic pressure, resulting, for example, from a neoplasm or aneurysm. Ehrlich, Ballon, and Graham reported a case in which mediastinal decompression aided a patient suffering from superior vena caval obstruction caused by mediastinal Hodgkin's disease. The patient operated on by Ochsner and Dixon derived great benefit from the separation of adhesive bands surrounding the thrombotic superior vena cava. We wish to report 3 cases in which the patients have been operated on at the Mayo Clinic recently. Two of these had what was believed to be thrombosis associated with constricting bands, and the third had only constriction as a result of tuberculous mediastinal glands.

One case (Case 2) has been reported previously by Rutledge and Gray. It is repeated herein for the sake of completeness, since additional follow-up notes have been made.

REPORT OF CASES

CASE 1 A housewife, aged 37 years, came to the clinic in May, 1939. She had been perfectly well until the onset of her present illness, except for injuries sustained in a minor automobile accident in November, 1937. At that time she had received a slight contusion of the anterior thoracic wall which inconvenienced her for only one day. In September, 1938, she had begun to complain of a sensation of fullness in her throat and a slight swelling of the face. The symptoms were exaggerated by exercise and by bending forward. She gradually became worse and was unable to sleep, unless she was propped up on two or three pillows, because of the sensation of tightness in her thorax and throat. Dyspnea and a mild degree of cyanosis made their appearance. Three months prior to her admission to the clinic she had noted that the veins of her chest, arms, and face were becoming more prominent.

On physical examination edema (graded 3 on the basis of 1 to 4) of the eyelids, neck, and upper extremities was found to be present. The veins of the thorax were dilated and

prominent as were the venules along the anterior costochondral margin (Fig. 1). A soft enlarged node was palpable in the left axilla. Roentgenologic examination of the thorax revealed a shadow on the right, above the arch of the aorta, which was interpreted as being an accentuation of the shadow cast by the vena cava. The direct venous pressure in the right arm was 336 millimeters of water and in the left, 330 millimeters. The remainder of the physical examination and laboratory tests revealed no abnormal findings.

A clinical diagnosis of superior vena caval obstruction probably associated with mediastinal fibrosis was made.

It seemed advisable to secure a specimen of the enlarged node in the left axilla for biopsy before mediastinal exploration was undertaken. On May 5, 1939, the node was removed through a small incision in the left axilla. The pathologist reported it to be an inflammatory lymph node.

On May 23, 1939, exploratory mediastinotomy was carried out under anesthesia produced intratracheally with gas and ether. Exposure was accomplished by the usual U shaped incision, the right breast being reflected upward and medially. The pectoralis major muscle was cut across over the third interspace anteriorly, the pleural space opened and the ribs were reflected with the retractor. A hard tumor-like structure could be felt in the region of the superior vena cava, through the mediastinal pleura. This started just proximal to where the superior vena cava dipped behind the pericardial fold and extended upward for approximately 4.5 centimeters, it was roughly 2.5 centimeters in diameter and almost bone hard in its consistency. More definite exposure being obtained by incising the mediastinal pleura, a band like structure was observed which seemed to be constricting the vena cava. This was split longitudinally to a depth of approximately 3 millimeters, and a portion was sent to the laboratory for histopathological examination. It did not seem advisable to carry the dissection further, lest uncontrollable hemorrhage result. Anatomical closure of the incision was accomplished after reflation of the lung. The tissue which was removed proved to be fibrous inflammatory tissue. A transfusion of 500 cubic centimeters of citrated blood was administered slowly during the operation.

Immediately after operation the patient was placed in an oxygen tent, where she remained for 4 days. Roentgenological and physical examination of the thorax on May 31, 1939, showed evidence of the presence of fluid in the base of the right lung. However, as the fluid was thought to be of small amount and as the patient was having no respiratory difficulties, thoracentesis was not performed. Determinations of direct venous pressure on May 27 and April 6 were 250 millimeters of water. The patient progressed unusually well and was dismissed from the hospital on the seventeenth postoperative day. She left for her home, a distance of approximately 800 miles, on the twenty-first postoperative day.

Her referring physician was kind enough to keep us informed as to her subsequent progress. On July 14, 1939, he found her venous pressure to be 240 millimeters of water and on July 17, 253 millimeters. She had only a slight remaining fullness of the face and was able to lie flat in bed without the choking sensation which had been her chief complaint. The patient wrote that she was "beginning to feel like her old self again."

CASE 2 The patient, a coal miner, aged 27 years, first registered at the clinic in January, 1939. He complained of swelling and flushing of the face which had been noticeable for about 14 months. He had had several attacks of pneumonia before he was 11 years of age. He stated that on November 11, 1937, he had suddenly noticed that if he used his arms actively or stooped, his face became flushed

venous pressure occurred in dogs in which obstruction had been accomplished above the orifice of the azygos veins, whereas in those with occlusion of both vena cava and azygos vein high venous pressure was maintained for long periods.

The collateral circulation, following occlusion of the superior vena cava, has been described by various investigators, such as Hallett, Fischer, Carlson (3), Blaslogame and Hinshaw and Rutledge and others. On the development of an efficient collateral circulation depends the future health of the patient and his ability to return to a gainful occupation. The anastomotic route utilized is determined largely by the situation of the occlusion, as has been brought out by Carlson. The systems available for shunting the blood around the obstructing lesion in the vena cava may be divided into a superficial system and a deep system. The superficial veins include the thoraco-epigastric, superficial epigastric, and the superficial plexus of veins of the thorax and abdomen, and the deep veins involved are the internal mammary azygos, hemiazygos, accessory hemiazygos, anterior and posterior mediastinal, intercostal, pericardophrenic, phrenic, superior and inferior epigastric, lumbar and deep veins of the back. Carlson (2) demonstrated experimentally in dogs that when obstruction above the junction of the vena cava with the azygos vein occurred, the azygos system was a very important path for the return flow of blood to the heart and that the abdominal collateral vessels were not well developed. In the presence of obstruction, including the azygos vein, the flow of blood in the remainder of the azygos system is evidently reversed and the superficial and deep abdominal collateral vessels carrying blood to the femoral and iliac veins or to the inferior vena cava are therefore much more prominent than normally.

Study of the collateral channels developed will enable the surgeon to localize the obstruction in a large percentage of cases, as has been emphasized by Hinshaw and Rutledge. They stated that in the presence of obstruction occurring above the level of the orifice of the azygos veins, a marked plexus of large veins may be seen over the sternum, often clearly connecting with the perforating branches of the internal mammary vein. It is apparent that the blood is seeking a route to the intercostal vessels and thence to the azygos system. Since this is a relatively efficient route of communication venous pressures are not so high and symptoms not so severe as in the instances in which other routes are necessary.

If the superior vena cava and its azygos tributaries are obstructed, it becomes necessary for

the blood from the upper half of the body to be returned to the heart through the inferior vena cava. In patients who have such obstruction, large dilated vessels are seen extending from the thorax to the lower parts of the abdomen and groin. There is a reversal of the flow of blood in these vessels which is easily demonstrable. The blood in a segment of vein is pressed out, and both ends of the segment are compressed by the index fingers. Release of the lower finger causes the vein to fill slowly or not at all whereas on release of the upper finger the vein refills almost instantly. Since this collateral route to the inferior vena cava is long and difficult, venous pressures are high and symptoms are marked. Occlusion of the superior vena cava below the termination of the azygos system manifests itself clinically in a similar way.

Hinshaw and Rutledge have called attention to the value of thorough inspection of the thorax for those patients suspected of having mediastinal lesions. They have noted small, superficial, very tortuous groups of dilated venules which make their appearance along the anterior costochondral margins of patients who have obstructing lesions within the mediastinum. These differ in appearance from the large dilated varicosities seen over the thoracic wall, and may be the first objective signs of mediastinal disease hence their great clinical importance. Their presence is sufficient indication for a thorough roentgenological study of the thoracic cavity.

Laboratory aids in the diagnosis include estimations of direct venous pressure, determinations of the circulation time, and, of course, roentgenograms of the thorax. It is particularly important to follow the direct venous pressure of these patients for whom surgical intervention is contemplated. We believe that only those individuals who show progressive increases in their venous pressures over a period should be subjected to mediastinotomy. The circulation time, as measured by the dehydrocholic acid (dechole) method, will be found to be prolonged in the presence of obstruction of the superior vena cava, because the blood is compelled to take a circuitous route in its return to the heart. The value of making roentgenograms of the thorax need not be mentioned.

We are again indebted to Ochsmier and Dixon's excellent review of the literature for the mortality figures for patients suffering from thrombosis of the superior vena cava. Of the 120 collected cases, 85 patients died. In those cases in which thrombosis of the superior vena cava was caused by aneurysm the mortality rate was 75.3 per cent in those in which the condition was

Fig 1 Case 1 Infra red photograph showing marked tortuosity of the superficial veins of the neck and thorax

veins of the right and left arms were, respectively, 294 and 276 millimeters of water, whereas the pressure in the left greater saphenous vein measured only 48 millimeters of water. Reactions to the flocculation test for syphilis were negative. Results of other routine laboratory tests added nothing of interest.

Fig 3 Artist's conception of the release of an inflammatory constricting process which had practically completely occluded the lumen of the superior vena cava below the orifice of the azygos veins. The constricted area has been released by separating the fibrous band. A U shaped incision beneath the breast may give better exposure and cosmetic results than that shown by artist.

Fig 2 Case 2 Infra red photograph showing marked dilatation and tortuosity of the veins of the chest, arm, and neck.

The diagnosis of incomplete superior vena caval obstruction was made. It seemed best to follow the patient's progress a short time by means of determinations of venous pressure, since there had not been much progression of the symptoms since their onset.

The patient returned to the clinic within one month, as had been requested of him. His symptoms had definitely progressed and one week before his return he had had an acute episode of edema. His collar size had increased from $14\frac{1}{2}$ to $16\frac{1}{4}$ inches (35 to 40 centimeters). The direct venous pressures in both the right and left arms were 394 millimeters of water. Because of the progression of symptoms it was deemed advisable to explore the region of the superior vena cava.

Fig 4 Case 3 Infra red photograph showing the distention of the right and left external jugular and right and left cephalic veins, together with generalized venous tortuosity.

and swollen. At first these symptoms subsided shortly after he stopped such activity but within a month they seemed to be present continuously. When he attempted to work, the swelling increased and he noticed bluish discoloration of the face and neck. In April, 1938, he first noticed enlargement of the veins of his neck, chest, and arms. These had continued to enlarge to the time of his admission. In December, 1938, the patient had to stop work because of sensation of choking when he attempted to do anything strenuous. Edema of the lower extremities had not been present and he had no other complaints.

On physical examination at the clinic the patient's face and neck appeared to be flushed and swollen. Slight activity such as bending over several times, aggravated the symptoms. There was marked distention of the veins of his chest, arms, neck (Fig. 1) and especially of the angular veins of the face. The direction of blood flow in the veins was toward the umbilicus. The clinical observations referable to the heart were not remarkable. Roentgenological examination of the thorax revealed evidence of slight thickening of the soft tissues about the vertebrae on the left side and exaggerated pulmonary markings, but did not reveal any calcification of the pericardium. The electrocardiographic tracing was that of normal heart. The direct venous pressure in the right arm was 335 millimeters of water and in the left, 345 millimeters. Normal venous pressure is between 40 and 50 millimeters of water. The pulmonary circulation time, measured after the administration of dehydrocholic acid preparation (dechofin) as 20 seconds. The average normal time is about 14 seconds. Results of other laboratory tests were negative.

It was believed that the patient was suffering from obstruction of the superior vena cava between the azygos vein and the entrance of the vena cava into the right auricle, possibly postinflammatory condition. Roentgen therapy was given, and the patient was sent home for one month.

On his return on February 2, 1939, the patient stated that his condition was about the same, but that in addition to the previously mentioned complaints, he had had three attacks of severe jerking movements of the left arm and leg which had lasted about one minute each. He did not lose consciousness when these episodes occurred. Roentgenological examination of the skull and examination of the eyes with funduscscope revealed nothing abnormal. On neurological consultation the attacks were thought to be Jacksonian seizures which probably had vascular basis. The direct venous pressure in the right arm was 434, in the left, 416, and in the right ankle, 92 expressed in millimeters of water. After consultation, it was decided that in view of the progression of the condition, the patient was entitled to surgical exploration.

Exposure as accomplished by making an incision from the upper portion of the anterior axillary line to the supra-sternal notch (Fig. 2). The skin and subcutaneous tissues overlying the right pectoralis major muscle was reflected upward and down on the line between the two points, and

linear incision was made across the pectoralis major muscle over the third rib and cartilage. The medial point of the incision through the muscle as then carried downward for approximately 3 inches (7.6 centimeters) along line which was about 1 inch (2.5 centimeters) from the insertion of the muscle. The triangular pieces of muscle were then reflected downward and outward and approximately centimeters of the third rib, together with approximately 3 centimeters of the costosternal cartilage of this rib, as removed. The cartilages of the second and fourth ribs were divided to permit greater exposure and dissection as then carried down to the pleura. The pleura was reflected laterally and extrapleural exposure of the

mediastinal structures was accomplished with some difficulty because of the presence of moderate quantity of fibrous tissue in this region. A small rent in the pleura allowed the right lung to collapse, and greater visualization of the mediastinal structures as obtained. Beginning about 2.5 centimeters above the pericardial reflection, there was an extremely hard tumor within the lumen of the superior vena cava, approximately 3 centimeters in its largest diameter the lowermost portion of this tumor extended beneath the pericardium. Evidence of extraluminal intonation was not found. An elongated constricting band, approximately centimeters in width, which compressed the superior vena cava, was divided so that the vena cava dilated at the point of previous constriction (Fig. 3). A small lymph node from the tissue immediately adjacent was removed and sent to the pathological laboratory for histopathological examination. It was found to be inflammatory. A small portion of the constricting band as removed and this also as found to be inflammatory tissue. Because the obstructing process was entirely within the superior vena cava and could not be removed, it was thought best to discontinue the exploration. The small rent in the pleura was closed, the right lung reinflated by means of positive pressure, and aastical closure of the wound was accomplished.

For the first 5 days immediately after the operation there was considerable swelling of all of the soft tissues of the upper portion of the thorax, neck, and arms, particularly the tissues of the left arm. This as so marked that it was impossible for the patient to flex the left arm. The

moose pressure in the left arm during this period was higher than any pressure the manometer could register, that is more than 500 millimeters of water. After the first week the swelling gradually subsided and the pressure within the veins of the arm decreased concomitantly. At the time of the patient's dismissal from the clinic, which happened on the thirty-second postoperative day, direct venous pressure of the arm had decreased to 390 millimeters of water. The veins on the upper portion of the thorax were much less prominent and in general the patient had remarkably improved.

The patient returned to the clinic for re-examination in June, 1939, as had been requested of him. His improvement had continued and for a month he had been able to return to somewhat less strenuous job at the coal mine. He had experienced no more Jacksonian seizures and was practically free of edema of the face and arms except after rather marked exertion and bending forward. The direct venous pressure in the right arm measured 378 millimeters of water. This patient was considered to have achieved an excellent functional result.

CASE 3. A mechanic, aged 33 years, was first seen at the clinic in March, 1939. He stated that for the past 9 months there had been intermittent swelling of his face, neck, and arms, occurring after exertion. Cyanosis of the lips, blue of the ears, and finger nails could accompany the edema. The symptoms were relieved by rest and they had not progressed much in severity. At times the attacks are accompanied by lightheadness and dizziness. The patient's physician at home had made presumptive diagnosis of obstruction of the superior vena cava and had removed gland from the left axilla which proved to be inflammatory in nature.

On physical examination, slight degree of edema of the face and neck was noted. After the patient had exercised, the edema became much more marked, and distention of the right and left external jugular and right and left cephalic veins became very apparent (Fig. 4). No abnormal structures could be localized in the mediastinum on roentgenological examination. The venous pressures in the

$\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$

Fig. 5. Constriction of superior vena cava by mass of calcified tuberculous lymph nodes; left, arrow points to portion of vena cava constricted; b, section of tuberculous mediastinal lymph node. Hematoxylin and eosin stain $\times 100$.

On May 2, 1939, mediastinotomy as performed under gas-ether anesthesia supplemented by pentothal sodium given intravenously. Exposure as accomplished through the usual incision. A hard tumor approximately 3 centimeters in length, was found in the region of the superior vena cava, proximal to the pericardium. On further dissection it was found that the parietal pleura was densely adherent to this, as were the other surrounding structures. These were dissected free with extreme difficulty, and constricting mass, alone hard in nature was noted. This mass was split end to end on each side so as to release the constriction at this point. It could not be definitely determined whether there was thrombosis within the vein or whether the mass was entirely extraluminal. A lymph node from the adjacent region was sent to the laboratory and found to be an inflammatory node. A small portion of the stone-hard, constricting mass proved also to be inflammatory tissue on microscopic examination. During the dissection moderate amount of hemorrhage as encountered. Plastic closure of the wound was accomplished.

On the second postoperative day the patient suffered rather severe shock and succumbed.

On postmortem examination the superior vena cava was found to be occluded to approximately 80 per cent of its normal size by pressure caused by mass of calcified tuberculous lymph nodes (Fig. 5a and b). The other anatomical diagnoses were healed tuberculosis of the liver and spleen, accessory pancreas of the pylorus, postmortem autolysis of the cardia of the stomach, adenoma of the adrenal glands, arteriosclerosis (graded on the basis of 1 to 4), hemorrhagic edema of the lungs with bronchopneumonia, diverticulum of the sigmoid and hemorrhage (200 cubic centimeters) into the right pleural cavity.

It is of interest to consider the causation of the obstruction in the cases just presented. Causation of the thrombosis in the first case is not definitely known. It seems hardly probable that the minor injuries of the thorax which the patient sus-

tained a year previous to the onset of her symptoms could have been the cause of the mediastinal fibrosis and the thrombosis of the vena cava. It is more likely that this patient at some time had experienced tuberculosis of the mediastinal lymph nodes or nonspecific mediastinitis.

It would appear that the second patient had mediastinitis accompanying one or more of his attacks of so called pneumonia with resulting fibrosis within the mediastinum and thrombosis of the superior vena cava.

On postmortem examination it was discovered that the third patient had suffered from compression of the superior vena cava by calcified tuberculous lymph nodes, without accompanying thrombosis.

It is also of interest to speculate as to why the release of constricting bands should result in clinical benefit in those cases in which definite thrombosis occurs within the lumen of the vena cava. Duval was of the opinion that removal of the constricting perivascular tissue permits opening of the already canalized channels within the thrombus, these vessels having been previously maintained as nonfunctioning canals because of the external pressure exerted by the encapsulating perivascular cicatricial tissue.

SUMMARY

Three cases of constrictive occlusion of the superior vena cava in which the patients were treated by operation have been reported. In 2 of

Fig 1 In a man, aged 55 years, with squamous cell epithelioma grade 4 on the posterior surface of the epiglottis extending down into the larynx and producing edema at the base of the tongue a preliminary tracheotomy was made, the epiglottis and growth were removed with diathermy, and emanation seeds were inserted into the base. Further radium seeds were inserted into the base of the tongue and epiglottis with no evidence of recurrence for 2 years

laryngoscopy when lateral or subhyoid pharyngotomy, which gives much better exposure for the larger growths, is indicated. However, many lesions, particularly the highly malignant tumors, that cannot be removed by purely surgical procedures, can be treated with the aid of suspension laryngoscopy (Figs 3 and 4)

Fig 3 In a man, aged 60 years, a squamous cell epithelioma grade 4 of the epiglottis and base of the tongue was removed after preliminary tracheotomy, July 2, 1934 and radium points were inserted into the growth. The patient has had no recurrence for six years

SUSPENSION LARYNGOSCOPY IN THE TREATMENT OF MALIGNANT DISEASE OF THE HYPOPHARYNX AND LARYNX

GORDON B. NEW, M.D. F.A.C.S., and HOWARD E. DORTON, M.D. Rochester, Minnesota

DURING the eleven year period, 1927 to 1937 inclusive, a selected group of 38 patients with malignant disease of the hypopharynx and larynx have been treated at the Mayo Clinic with the aid of suspension laryngoscopy. Surgical diathermy and radium emanation seeds have been employed, and, in addition, external irradiation has been used at times.

While suspension laryngoscopy has been used for many years, its value in the treatment of malignant diseases of the hypopharynx and larynx is not generally known. We feel that carefully selected patients can be taken care of with less surgical risk when laryngeal suspension is employed. Immediate histological diagnosis by the fresh frozen section is an essential part of this method.

Lynch did more than anyone else in this country to perfect and stimulate interest in suspension laryngoscopy. In 1928 he reported dissection with a knife of early intrinsic laryngeal epithelioma under suspension and recommended its use in certain selected cases.

Kilham in giving the Semon lecture stated that Mayer removed an epithelioma of the epiglottis in 1914 under suspension laryngoscopy but said that such cases ought to be selected with care.

At the Mayo Clinic we have used suspension laryngoscopy for many years and feel that it has a definite place in the treatment of cancer of the hypopharynx and larynx. However the apparent lack of widespread knowledge of its usefulness is shown by a statement of Thomson in 1939 when he said, operation *per vias naturales* is now only of historical interest, though pathologically of some importance, and he attributed the occasional rare instances of cure by this route to low grade lesions of minor extent.

SELECTION OF CASES FOR TREATMENT

Our series consisted of 38 cases of malignant disease in the hypopharynx and larynx in which

From the Section on Laryngology, Oral and Plastic Surgery, the Mayo Clinic, and the Department of Surgery, the Mayo Foundation.

Read before the meeting of the Academy of Ophthalmology and Otolaryngology, Cleveland, Ohio, October 7 to 9, 1940.

treatment had been given under suspension laryngoscopy during the years 1927 to 1937 inclusive. During this same period approximately 450 patients were operated on at the clinic for malignant disease of the larynx and hypopharynx. This brings out the fact that the cases in which treatment was given under suspension laryngoscopy are a selected group.

We have divided the cases into 5 groups depending on the location of the growth: (1) growths at the base of the tongue in the hypopharynx; (2) supraglottic growths; (3) intralaryngeal growths; (4) growths involving the lateral and posterior walls of the hypopharynx and (5) post-cricoid growths. Some of these lesions involved two or more of these sites, but we grouped them according to the place where the major part of the tumor was situated. As each one of these various groups presented different problems, the selection of cases for treatment in this manner must be discussed individually rather than collectively.

Growths at the base of the tongue in the hypopharynx that were part of carcinoma of the body of the tongue were not considered. Only primary growths at the base of the tongue in the hypopharynx were included. Growths in this location can be of three varieties: (1) adenocarcinoma, mixed tumor type which is usually a low grade tumor; (2) highly malignant squamous cell epithelioma of grade 3 or 4 that infiltrates into the tongue and that is an active growth; and (3) squamous cell epithelioma of low grade which does not infiltrate into the tongue but is an outgrowth from the surface of the tongue. All of these lesions are best taken care of under suspension laryngoscopy because of the difficulty of obtaining a direct view of them in a satisfactory way with any other method. Only an extensive lesion or extensive metastasis would prevent treatment in this group of cases.

The supraglottic growths consisted of those which involved the epiglottis alone or those that extend into the aryepiglottic fold, base of the tongue, or lateral wall of the pharynx (Figs. 1 and 2). Care should be taken not to attempt to treat lesions in this region under suspension

Fig 1 In a man, aged 55 years, with squamous cell epithelioma grade 4 on the posterior surface of the epiglottis extending down into the larynx and producing edema at the base of the tongue, a preliminary tracheotomy was made, the epiglottis and growth were removed with diathermy, and emanation seeds were inserted into the base. Further radium seeds were inserted into the base of the tongue and epiglottis with no evidence of recurrence for 2 years

laryngoscopy when lateral or subhyoid pharyngotomy, which gives much better exposure for the larger growths, is indicated. However, many lesions, particularly the highly malignant tumors, that cannot be removed by purely surgical procedures, can be treated with the aid of suspension laryngoscopy (Figs 3 and 4)

Fig 3 In a man, aged 60 years, a squamous cell epithelioma grade 4 of the epiglottis and base of the tongue was removed after preliminary tracheotomy, July 2, 1934, and radium points were inserted into the growth. The patient has had no recurrence for six years

Fig 2 Photomicrograph from same case as in Figure 1 $\times 180$

In our series the intralaryngeal growths selected for treatment under suspension consisted of tumors of low grade or those of limited extent

Fig 4 Photomicrograph from same case as in Figure 3 $\times 180$

Fig. 5 In situ view of the larynx in a man, aged 44 years, squamous cell epithelioma grade 1 at the base of the vocal cord along the anterior two-thirds of the left vocal cord as removed by means of surgical diathermy November 20, 1936, under suspension laryngoscopy with no recurrence for 3½ years.

on the anterior two-thirds of the vocal cord frequently a thickened leucoplakia with early epithelioma was taken care of in this manner (Figs. 5 and 6). For elderly patients, particularly those with hypertension, diabetes, or bronchiectases, for whom the risk from thyrotoxy is increased, removal of the lesion by intralaryngeal methods is justified if the lesion is small, of low grade and there is no fixation of the cord.

The growths, involving the lateral and posterior walls of the hypopharynx, are usually highly malignant tumors. They can be treated by the insertion of radium seeds into the lesion as well as by external irradiation. Tumors of the highly malignant type can be treated more successfully with radium than low grade tumors; consequently small lesions of low grade should be removed with surgical diathermy.

Of the postcricoid growths only two have been treated in this series with the aid of suspension

Fig. 6. Photomicrograph from same case as in Figure 5 X 25.

laryngoscopy. In most of these cases roentgen therapy with fractional doses accomplishes as much as any local treatment of the growth. It is only in the low grade lesions that we feel that external operation by the method of Trotter in which lateral pharyngotomy is performed, gives the patient any permanent benefit.

REVIEW OF CASES

The average age of the 38 patients was 57.4 years. The youngest was a woman aged 30 years, who had squamous cell epithelioma grade 1 of the middle third of the vocal cord, and the oldest was a man, aged 79 years, who had squamous cell epithelioma grade 4 of the base of the tongue.

TABLE II.—HISTOLOGICAL TYPE—
1927-1937 SERIES

Lesion	Histological grade	Patients		Length of life after treatment (years)	
		Total	Living last report, no recurrence	Completed	Survived

Fig 7 In a woman, aged 70 years, a lymphosarcoma of the base of the tongue at the level of the epiglottis was partially destroyed with diathermy on June 17, 1936, and radium points were inserted into the growth. She has had no recurrence for 4 years.

Fig 8 Photomicrograph from same case as in Figure 7. $\times 190$.

There were 4 women in this group, the ratio of males to females being 8.5:1. Three patients (79 per cent) had syphilis.

Ten lesions were situated at the base of the tongue, 12 were in the supraglottic region, 11 in the intralaryngeal region, 3 on the lateral and posterior walls of the hypopharynx, and 2 in the postcricoid region (Table I).

The most common symptoms in this group of cases were dysphagia and hoarseness. The symptoms, of course, depend on the location and extent of the lesion. Malignant lesions at the base of the tongue are frequently overlooked. The advanced lesions produce marked symptoms of pain, bleeding, and so forth, while the early lesions produce little discomfort. On this account, patients with epithelioma of the base of the tongue, epiglottis, and aryepiglottic fold usually have large lesions at the time of the first examination. Patients with early lesions of the supraglottic region frequently complain of a sensation of a foreign body in the throat while those with lesions on the vocal cords have hoarseness early and are frequently seen with a small lesion. Only 3 patients noticed enlarged glands in the neck, although 8 patients had enlarged glands in the cervical region at the time of examination.

THE METHOD OF TREATMENT

Pentobarbital sodium, $1\frac{1}{2}$ grains (0.1 gm), was administered by mouth an hour before the opera-

tion. The larynx was cocaineized with a 10 per cent solution of cocaine, and the patient was then anesthetized with sodium ethyl (1-methylbutyl) thiobarbiturate (pentothal sodium) given intravenously. A 2.5 per cent solution was used. A pharyngeal tube was inserted into one of the nostrils through which oxygen was administered throughout the procedure. The pentothal sodium was administered intermittently whenever necessary.

A flat spatula attached to the suspension apparatus was employed for the lesions at the base of the tongue. For lesions of the epiglottis the spatula picked up the base of the tongue and exposed the entire epiglottis and vallecula. For intralaryngeal lesions the spatula picked up the epiglottis, and the surgeon had a direct view of the entire glottis. In all cases a specimen of the lesion was removed, a fresh frozen section was examined, and immediate diagnosis was made. Results of microscopic examination of the tissue removed are given in Table II.

In cases of carcinoma of the base of the tongue and epiglottis or aryepiglottic fold, preliminary tracheotomy was performed. After recovery the laryngeal suspension was done, and treatment was performed. For growths involving the base of the tongue (Figs 7 and 8), radium emanation seeds were inserted into the lesion after the use of surgical diathermy. If the lesion was of limited extent, the entire treatment was completed with surgical

Fig. 9. 1. man, aged 45 years, squamous cell epithelioma grade 4 of the entire base of the tongue and large metastatic mass measuring 5 by 3.5 by 3.5 centimeters in the cervical region. As treated under suspension laryngoscopy August, 1933 and radon seeds are inserted into the growth. This is followed by roentgen treatment applied externally to the neck. The patient is alive and well and without recurrence seven years after treatment.

Fig. 10. Photomicrograph of specimen from the same case as in Figure 9. $\times 80$.

diathermy alone. The supraglottic lesions were destroyed with a long protected diathermy point. This is a long needle covered with Duco varnish so that only the distal end of the needle is exposed. The epiglottic growths were removed piecemeal or in one piece with the Bovie surgical diathermy unit. The intralaryngeal lesions were removed with the diathermy point. No attempt was made in the primary laryngeal lesions to use radium in addition to diathermy except in unusual circumstances, for we felt that lesions extensive enough to need radium in addition to diathermy are better treated by means of thyrotomy.

In addition to treatment under suspension radium or roentgen rays were applied to the outside of the neck, especially in cases of highly malignant growths at the base of the tongue.

RESULTS

The results of the treatment of malignant disease of the hypopharynx in the past have been very poor. The Trotter operation has produced some very striking results, but they are few. Recently fractional doses of roentgen rays as well as radium used externally have been of considerable benefit. Lenz in discussing Martin's paper reported 31 cases of hypopharyngeal malignancy. 69.3 per cent. of his patients were apparently free of disease, but the length of time these patients have lived since treatment was not stated. Four of these patients had growths involving the epiglottis.

Of the 17 patients with malignant disease of the hypopharynx including the base of the tongue (Figs. 9 and 10) supraglottic region, lateral and posterior walls of the hypopharynx, and post-cricoid region we were able to trace 16, and 14, or 51.8 per cent. of the patients who were traced were alive and well.

Of the 11 patients with intralaryngeal lesions, 10 were traced and 9 or 80 per cent. were alive and without recurrence. These patients had small, low grade lesions which account for this very high percentage of cures.

TABLE III.—THREE AND FIVE YEAR SURVIVALS

Period after treatment	Patients treated	Patients traced	Survived beyond indicated period	
			Number	Per cent.
or more years		37		
1 or more years	17	7	10	29

*The 3 year group comprises the patients treated 10 or more years prior to the time of inquiry. That is, 12, 15 or earlier. The 5 year group comprises the patients treated 5 or more years prior to the time of inquiry. That is, 1934 or earlier.

Nine of the traced patients, or 25 per cent, died of cancer, the majority within a year and a half of the final treatment. One of the group now dead lived 7 years, and another of the group, 6½ years.

There was 1 postoperative death, the patient died of bronchopneumonia 8 days following treatment of an epithelioma at the base of the tongue. The patient did not have a preliminary tracheotomy.

The 3 and 5 year survivals are shown in Table III. Of 31 patients treated and traced for 3 or more years (operations were performed in 1936 or before), 23, or 74 per cent, lived more than 3 years. Of 17 patients treated and traced for 5 years (operations were performed in 1934 or

earlier), 10, or 59 per cent, lived more than 5 years. In the series there were 3 patients who have lived more than 9 years following treatment, and all of these are living at the time of this report (1940).

THE DEMONSTRATION OF MYCOBACTERIUM TUBERCULOSIS IN ANORECTAL ABSCESS

JOSEPH E. POTTENGER, M.D. and F. M. POTTENGER, Jr. M.D.
Monrovia, California

An abundant literature is available reporting various diagnostic laboratory procedures for the demonstration of *Mycobacterium tuberculosis* in fistula in ano. Recently Buie Smith, and Jackman reviewed the subject calling attention to the almost universal failure to demonstrate the organism by direct staining methods. They recommended guinea pig inoculation. Quite recently Joynt confirmed the general conclusions of previous writers and employed culture methods in place of the guinea pig. In relation to the antecedent condition, anorectal abscess, demonstration of the organism by direct microscopical methods has not been reported with any important degree of success. In institutions where patients are continuously under observation we may anticipate the spontaneous rupture of these abscesses by aspirating the contents. During the past 9 years we have successfully aspirated 16 of a total of 20 abscesses under observation.

CLINICAL MATERIAL

This report is concerned with the investigation of 22 abscesses from 9 patients. All patients furnishing material for examination had positive sputum except 1 whose pulmonary history was unknown, as the specimen was sent in by an outside physician. One patient had 3 distinct abscesses form over a period of 1 year. Another had 2 abscesses during a 4 months' period.

Sixteen abscesses were successfully aspirated. Rupture during preparation for aspiration occurred 4 times and spontaneous rupture occurred from week to 4 months before investigation in 2 instances.

PROCEDURE

The syringe and needle No. 6 were sterilized at 220 degrees C. dry heat for 1 hour. The investigation of the material was made with the dilution-flotation procedure (3) and guinea-pig inoculation. All animals were tested before they were used with 0.1 cubic centimeter purified protein derivative second strength. The same dose was given as a diagnostic test on the twentieth day after inoculation.

From The Pottinger Sanatorium, Monrovia, California

The pus diluted 10 times with 0.5 per cent sodium hydrosulfide was shaken in a strong shaker for 5 minutes and set at 37 degrees for 1 hour or in case contaminating organisms were present, for 2 hours. Thorough homogenization was accomplished by 10 minutes shaking. The centrifuge was employed at 1000 revolutions per minute for 2 minutes, to throw down undigested tissue fragments. The upper third of the solution was pipetted off, placed at 55 degrees C. for 30 minutes to complete the digestion process and used for dilution-flotation. The final dilution with distilled water was made so that the amount of the original material contained in the fraction would be diluted 100 times. (On account of the high protein content of this type of material it is necessary to dilute to a much greater degree than is necessary in the case of sputum.) From 0.5 to 1 cubic centimeter of xylol was added, and the mixture shaken for 10 minutes. Films were made from the xylol layer by means of a capillary pipette. The exact number of organisms found in a 10 minute search was recorded if present to the extent of one in two fields or less.

For guinea pig inoculation the remaining two-thirds of the digested specimen was employed. It was neutralized with 3 per cent hydrochloric acid in the presence of brom-thymol-blue, and injected subcutaneously in divided dosage in 2 or more regions. (If all the inoculum is given in one region, pyogenic ulceration may occur early and expel the organisms before infection takes place. Ulceration of all inoculation sites in case of divided dosage is a rare event.) We had but 1 early pyogenic abscess in the series. The animal, however was positive. In 9 animals the inoculation was made intraperitoneally. Not a single animal was lost by death due to other causes.

RESULTS OF INVESTIGATION

Of 20 abscesses and recently formed sinuses investigated 4 showed from 2 to 1 organisms per field, so that confirmation by inoculation was not needed. The results obtained by dilution-flotation and guinea-pig inoculation of material obtained from the remaining 16 abscesses are tabulated in Table I. The table presents 3 groups of

TABLE I—FINDINGS BY DILUTION-FLOTATION AND GUINEA-PIG INOCULATION IN 18 ANORECTAL ABSCESSES AND RECENTLY FORMED FISTULAS IN 14 KNOWN TUBERCULOSIS PATIENTS

Specimens	No of examinations	Average amount c.cm	D.F. + G.P. +	D.F. - G.P. -	D.F. - G.P. +	D.F. + G.P. -
Aspirated	13	2.66	12	1	0	0
Ruptured at operation	4	0.49	2	1	1	0
Ruptured 4 mos before investigation	1	0.01	0	0	1	0
Totals	18		14	2	2	0

D.F. dilution flotation
G.P. guinea pig

results. The first consists of 13 successfully aspirated abscesses averaging 2.66 cubic centimeters. The second consists of 4 abscesses which ruptured into the anal canal under pressure from the speculum resulting in much loss of material and averaging 0.49 cubic centimeter of material recovered. The third group represents a single specimen in which a very small amount of serous discharge was obtained from a fistulous tract which had formed 4 months previously.

In the first group of successful aspirations dilution-flotation and guinea-pig inoculation were in 100 per cent agreement, 12 positive and 1 negative result. In the second group of 4 abscesses rupturing under pressure, agreement resulted in 3 instances, 2 positive and 1 negative, and in the fourth instance in which only 0.05 cubic centimeter of material was obtained, dilution-flotation was negative but the guinea-pig was positive. In the third group dilution-flotation was negative and the guinea-pig was positive.

The total of the 3 groups shows 18 specimens in which dilution-flotation and inoculation were in agreement 16 times. Fourteen specimens were positive and 2 negative. It should be noted that the 2 failures by dilution-flotation occurred with materials small in amount, following spontaneous rupture.

TABLE II—RANGE OF THE NUMBER OF ORGANISMS FOUND IN 18 SPECIMENS POSITIVE BY DILUTION-FLOTATION

	Times Found
1 in 2 fields to 10 per field	8
Organisms found in 10 minute search	
15 to 79	1
1 to 14	9

Elsewhere (3, 4) the relative sensitivity of homogenized smears counterstained with strong

methylene blue, with picric acid, and the same material treated by dilution-flotation counterstained with picric acid is given as 1, 5, 5, and 80, respectively. Applying these ratios to Table II, 8 of the 18 specimens, or 44.4 per cent should be positive by Ziehl-Neelsen with methylene blue counterstain. If picric acid is used, another specimen should be positive, making 9 positives in a total of 18 or 50 per cent. Nine specimens should be found positive only by dilution-flotation. This is the group in which the organisms are so rare that they may be found by Ziehl-Neelsen only by prolonged search of an hour or more. Even with the 15-fold enrichment attained by dilution-flotation only 4 organisms were found in 1 specimen in 1 hour's search. In the remaining specimens the organisms were found during the first 5 minutes' search. Ziehl-Neelsen counterstained with picric acid was carried out in 7 of the 18 specimens, 4 of which, or 57.1 per cent, were positive. This percentage agrees well with the probable percentage deduced from the known sensitivity ratios.

The actual number of organisms found in the 9 specimens per cubic centimeter of material is small. Corper established about 100,000 organisms per cubic centimeter as the lower limit of sensitivity of the Ziehl-Neelsen method and since dilution-flotation with picric acid counterstain is 80 times more sensitive, a single bacillus found in 10 minutes' search would indicate $100,000 \div 80 = 1250$ organisms per cubic centimeter. The number of organisms, 1 to 14, found in a 10 minute search would indicate the presence of 1250 to 17,500 organisms per cubic centimeter of original material investigated.

EVALUATION OF STUDY

In view of the unprecedented success with which we have demonstrated Mycobacterium tuberculosis in this series of abscesses, we wish to point out the causes of failure of earlier workers. First, the selection of the optimum time for aspiration has not been duly considered. It is well established that the number of organisms in tuberculous lesions increase greatly at the time of caseation and liquefaction. Following removal of the abscess contents by spontaneous rupture, the organisms decrease rapidly so that their demonstration is difficult. Second, an adequate enrichment and a light counterstain is absolutely necessary for maximum results.

Undoubtedly many, perhaps most, of these abscesses rupture spontaneously before the surgeon is consulted, thus the best conditions for direct and immediate investigation have disappeared.

It is evident that a method that can give a definite diagnosis within 2 hours after the specimen is received by the laboratory offers a distinct advance over former practice. In 1 of these cases a negative result by dilution-flotation led us to refrain from surgical procedure. The abscess healed spontaneously and 2 months later the guinea-pig confirmed the negative findings.

SUMMARY AND CONCLUSION

A comparison of the results obtained by dilution-flotation and guinea-pig inoculation in the demonstration of *Mycobacterium tuberculosis* in 18 anorectal abscesses is presented.

The two methods were in 100 per cent agreement in 13 abscesses aspirated by needle. Twelve were positive and 1 was negative by both. Under less favorable conditions in which the abscesses ruptured spontaneously with much loss of ma-

terial, they were in agreement in result in 3 of 5 abscesses investigated. Two were positive and 1 was negative by both. In the 2 other abscesses dilution-flotation was negative and inoculation was positive.

Dilution-flotation with picric acid counterstain offers a means for the immediate diagnosis of anorectal tuberculosis in the abscess stage, or its probable exclusion.

that particular branch of nursing. A nurse not possessed of such an aptitude and yet required to serve as a surgical nurse will suffer mentally because of her lack of experience and her ineptitude. In fact, she will be more of a hindrance than a help to the surgeon and indeed, in some immeasurable degree, may be responsible for increased morbidity or mortality percentages.

It is an accepted fact that a surgical operation is a serious undertaking and therefore anyone taking part in such an undertaking must be capable, well trained and experienced. If it is required that those who desire to become surgeons take special training to demonstrate their fitness to do surgery then similar standards of training and requirements should be established for the training of that very important part of the surgical team—the surgical nurse. Just as the prospective surgeon must take postgraduate training in surgery so should the nurse wishing to qualify as a surgical nurse be compelled to take postgraduate training in operating room technique. When, as part of their training, undergraduate nurses are assigned to the operating room, they should be under the supervision of trained and experienced operating table nurses and should work only as second nurses. In such a position they will not handicap the operating surgeon; they will be more calm and hence be better able to learn under the direction of one with sufficient experience and knowledge to teach them. Unfortunately it is true that the less experienced the surgeon the more apt he is to have to work with a relatively inexperienced and inept surgical nurse, despite the fact that he should be relieved of any confusion or lack of co-operation and should be free to concentrate exclusively on the operative procedure.

The time is not far distant when both that surgeon and that hospital will be out of step

with the times who do not include in operating teams an anesthetist who is qualified to employ all of the newer developments in the administration of anesthetics, an assistant who is at least in the process of being trained to carry out all of the major surgical procedures, and an operating nurse who has been specially trained for a relatively permanent position.

FRANK H. LANEY

AN EVALUATION OF THE METHODS OF TREATMENT OF CRYPTORCHIDISM

THERE is a diversity of opinion among surgeons as to the best treatment for the undescended testis. Some believe that the ectopic gland is potentially malignant and should be removed. It should be said however that the undescended testis should not be considered a precancerous lesion as only about 2 per cent of such organs develop tumors (Human). Others believe that if left alone, most of these retained gonads will descend spontaneously. The reports of some investigators have indicated that the results from hormonal therapy are equally as good as, if not superior to those obtained by surgical treatment (orchiopepy). In formulating a rational plan of treatment of the undescended testis, one is influenced by the number and type of cases he has seen, his surgical experience and that of his associates, and the type of case that receives hormonal therapy.

It is an important question: What percentage of undescended testes descend spontaneously? If the majority of ectopic testes will eventually descend of their own accord as some investigators claim, the value of any kind of therapy is questionable.

There can be no doubt but that some aberrantly placed testes migrate to the scro-

tum of their own accord (Drake, Williams, Johnson) There is a difference in the reported incidence of ectopy before and after puberty According to Johnson, Williams and Drake, the incidence of cryptorchidism in younger boys is 17 to 42 per cent, in adult men gonadal ectopy occurs in 02 to 03 per cent This may mean that the hormonal changes incident to puberty produce descent in a large percentage of cases However, another explanation may be the inclusion in the prepubertal group of a number of testes of the migratory or retractile type (physiological ectopy, pseudocryptorchidism, or ectopy *en retour*) It is important to differentiate true (anatomical) from the pseudo or physiological type of cryptorchidism, as many cases of the latter descend spontaneously into the scrotum at puberty There is no convincing evidence that testes anatomically retained by mechanical obstructions to descent ever descend spontaneously Moreover, the finding of cryptorchidism in adult men is irrefutable evidence that all undescended testes do not descend spontaneously

The treatment of undescended* testes by gonadotropic substances is generally recognized, but the results of treatment are varied Bigler, Hardy, and Scott and Nixon in their reviews of the early literature found that descent was said to occur in 60 to 75 per cent of cryptorchids treated with pituitary or pituitary-like extracts Later reports have been less enthusiastic The studies of Thompson and Heckel, Mimpriss, and Rea showed descent in only 16 to 31 per cent of ectopic testes treated by endocrine therapy The dosage and length of treatment with anterior pituitary-like substances is quite varied in the cases reported in the literature Thompson and Heckel wonder if the percentage of patients showing descent spontaneously at puberty would be the same as that following the use of

anterior pituitary principle before puberty Thus, as a result of hormonal therapy, descent of the testis would be obtained only in those cases in which the testes would descend normally at puberty

It is impossible to give a final estimate of the value of gonadotropic substance in the treatment of ectopic testes For one thing, the incidence of spontaneous descent is not accurately known Furthermore, it must be ascertained whether endocrine therapy causes descent only of those testes which would descend without therapy about the time of puberty Hormonal therapy may make it possible to differentiate between those testes which require surgical interference because of mechanical obstruction to descent and those that do not

Treatment of the retained testis may be deferred until the patient is nine to eleven years old, since the testis does not grow grossly or microscopically until puberty, (Wangensteen) If one cannot be certain that the case is one of pseudocryptorchidism or true undescended testis, there is no great harm in waiting until after puberty before instituting treatment The practice of delaying treatment too long is to be condemned, however, knowing how atrophic the testis becomes when left in an aberrant position

A course of hormonal therapy should be given first to see if the additional hormonal stimulus will cause the gonad to descend into the scrotum If no results are obtained, an orchiopexy should be performed From the experience at the University of Minnesota Hospitals, it may be said that (a) spontaneous descent of a true undescended testis is a rare occurrence, (b) that the results following the use of gonadotropic substance in cryptorchidism have been disappointing, and (c) that the most satisfactory treatment of ectopic testis is orchiopexy

CHARLES E. REA

TEXTS AND DOCUMENTS

TO A MEDICAL GRADUATE UPON BEGINNING HIS HOSPITAL INTERNESHIP

IN the main corridor of the Cook County Hospital beside the elevators that carry a never ceasing stream of doctors, internes, nurses, visitors, is a bronze plaque inscribed in memory of Christian Fenger. The interested reader cannot but wonder, "What sort of man was this to merit such recognition?" and the thoughtful interne may ask himself, "Could I accomplish anything to merit such a tribute from my successors?"

The story of Christian Fenger, of his life and of his contributions to surgery, and particularly to Chicago surgery, has been told many times¹—only recently in a beautiful tribute by Dr. James B. Herrick.² Everyone has dwelt particularly on his prolonged preparation for the practice of medicine, his indefatigable industry, his willingness to help young men. In Billings' words

"soon after his arrival in the country, he was persuaded by his countryman and friend, Dr. S. J. Jacobson, to locate in Chicago. Dr. Jacobson introduced Fenger to the members of the staff of the Cook County Hospital and he was invited to conduct a few autopsies at that institution. His scientific demonstration of pathological anatomy created such an impression that Dr. Isaac N. Danforth, who held the appointment of pathologist to Cook County Hospital, immediately tendered his resignation for the purpose of making the position available to Fenger. From the spring of 1878 until 1893, Fenger was the chief pathologist at the County Hospital, for 14 or 15 years the autopsy room at the County Hospital was the Mecca of medical students, internes, and members of the medical profession of Chicago who for the first time in the medical history of the Middle West had an opportunity to witness scientifically conducted autopsies and to learn the fundamentals of morbid anatomy and pathology.

"In 1879, Fenger served in the surgical wards for the various members of the surgical staff of the

hospital when they were absent from the city on vacations. This surgical service gave him the opportunity to introduce Listerism—antiseptic surgery—in the Middle West. In 1880 Fenger secured appointment with a regular surgical service in the County Hospital in which he continued for the next 12 years.

"From 1880 to 1884 he was curator of Rush Medical College Museum, in 1884 he was appointed professor of surgery in the College of Physicians and Surgeons, in 1893 he became professor of surgery in the Northwestern University Medical School, and in 1899 he became professor of surgery in Rush Medical College affiliated with the University of Chicago. He was surgeon in chief of the Passavant Memorial Hospital, the German Hospital of Chicago, and the Lutheran Tabitha Hospital from the time they were organized until his death. From 1893 to 1899 he was attending surgeon at the Mercy Hospital, Chicago, and from 1899 until his death, he was attending surgeon at the Presbyterian Hospital.

"he won success in practically every project undertaken. His knowledge of morbid anatomy and of pathology was phenomenal for that day and was attained by unremitting energy during his life in Denmark and Egypt and his earlier experience in the United States. This knowledge of pathology and of morbid anatomy made him one of the great surgeons of his time. He never became a brilliant operator, but what he lacked in operating skill was more than compensated for by thoroughness and knowledge of pathology. In diagnosis he was unsurpassed by any of his living contemporaries. He spoke five or more modern languages, but did not possess a ready command of any language. Nevertheless, he was a great teacher and though his speech was usually marked by halting words, he was able to impart knowledge to others with greater clearness than most teachers with fluent speech. He was especially fond of young men who showed by their every day lives that they had a thirst for knowledge and expressed this by purposeful, enduring work. He spent hours of his valuable time, both of the day and night, in the instruction of young medical

¹Frank Billings, *Surg. Gynec. & Obst.* 1922, 35: 365-369.
Alton Ochsner, *South M. J.* April 1938, 447-451.

²Proceedings of the Institute of Medicine of Chicago, 1941, 13: 318-319.

men in these interesting conferences he frequently forgot the passage of time in the apparent joy of teaching. It was through his influence that many of the young medical men of the period from 1880 to 1900 visited the clinics of Germany, Austria, France and England, and later became leaders in their chosen fields of work in the United States. While Fenger loved above every other thing in his professional life to help young men who were not afraid to work, he expressed an impatience with the frivolous and indolent men with whom he came in contact. Always he had the courage of his convictions and expressed them with blunt words which sometimes gave those unacquainted with him the idea of unfriendliness. But no man the writer has ever known was freer of envy or jealousy of others. Always he availed himself of every opportunity to express appreciation of the work of other men, provided it was characterized by honesty and efficiency. He was honest, intellectually and professionally. He was sincere and by nature simple in his deportment and daily life. He was free from cupidity and sympathetic with the poor, to each patient he applied all of the knowledge he possessed and all of the time necessary regardless of financial reward.

Fenger lived in Chicago 24 years. During that period of time he exerted an influence in scientific medicine unequalled by any other individual. It was due to his influence and particularly as a pathologist that there developed such men as Nicholas Senn, John B. Murphy, William J. Mayo, Lewis L. McArthur and many others celebrated as great surgeons, and Ludvig Hektoen, E. R. LeCount, H. G. Wells, and others recognized as great pathologists, and many practitioners of internal medicine throughout the Middle West and in Chicago.

Christian Fenger passed from this life on March 7, 1902, but though 50 years have passed, he lives today in the hearts and minds of hundreds of physicians and surgeons who were proud to call him master and he will continue to live through other generations by the work of his students and his pupils' students.

The rewards that came to Fenger were those that every doctor comes to prize above all others—the esteem, the affection, and the wholehearted admiration of his fellow practitioners.

Not long ago in a publication emanating from an interne group there appeared "Our Platform, and among other 'planks' the following:

Expansion of the educational program.

"Preferential consideration for our internes in making appointments for residencies.

"Financial remuneration for internes.

The contrast with the spirit and principles of action that motivated Christian Fenger's life struck me so forcibly that I was impelled to draw up a "platform" which seemed to me consistent with the spirit of a great institution. Perhaps I should call it "Resolutions Made on Beginning an Internship."

To be grateful for unlimited opportunity to expand my medical horizon in a relatively brief period of time and in unusually favorable surroundings. To appreciate the privilege and opportunity of following in the steps of Christian Fenger and Nicholas Senn or perhaps of Maurice Richardson, of Homans and Cabot or of Halsted and Oiler and Fluney. To emulate their example and to prove a worthy successor to them.

To co-operate with everyone on my service so as to render the most efficient possible care to the patients entrusted to me. As a junior to be loyal, prompt, ready for any task that will help to "make things go." As a senior to direct and organize the work of the ward so that the younger men will secure the maximum of training and experience so that the medical students who come to the hospital as clerks will strive to secure a place on our service so that the nurses will feel it is an opportunity and privilege to help care for our patients.

To treat with special consideration the patients who come under my care knowing that many of them are the world's less fortunate children and that they are in the hospital, not because of their confidence in my ability to help them, but because they have nowhere else to go.

To be sympathetic and kindly to relatives and friends, realizing that in the practice of medicine one must consider the family as well as the patient, and that unless I can gain and hold the confidence of both my efforts may be fruitless. To remember that the reaction of the responsible member of the family to a request for consent to postmortem examination of the baffling and unusual case that has not responded to treatment may depend entirely on the impression he has gained as to the degree and sincerity of my interest in the patients under my care.

To make an accurate record of the history and of the examination of each patient so

that the evidence may be complete and permanent To keep notes of important cases with names, dates, and diagnosis, so that I can recall them for reference when the occasion arises

To leave no stone unturned to make an exact and accurate diagnosis of every patient in my ward

To give every patient under my care the benefit of the best treatment that the hospital and modern medical science afford

To make a list each morning of the half dozen patients that require special care and attention for the next 24 hours if they are to recover from the serious illness they have contracted To explain the need for special care to the responsible nurses, so that their interest is quickened and their efforts directed with intelligence and effectiveness

To try to anticipate trouble and not to wait until catastrophe stares us in the face To provide a suitable donor and to be ready for blood transfusion before the patient is *in extremis*, to give the intravenous fluid before dehydration is obvious to the most casual observer To prepare my surgical cases properly for operation, to see that the necessary instruments and apparatus are available and in good order, to provide for the cast or splint or retention apparatus that may be needed after operation

To ask myself each evening before I leave the ward if there is something still undone that cannot wait until morning—some case of bleeding to check for evidence of recurrence, some splinted arm or leg to check for position or pressure of bandage or cast, some intravenous fluid to be given

To keep on my bedside table some journals and books, so that every evening before I turn off my light I can spend 20 minutes reading the *Journal of the American Medical Association*, *SURGERY, GYNECOLOGY AND OBSTETRICS*, the *Annals of Surgery*, or the life of Christian Fenger, of Robert Jones, of Osler—men after whom I would wish to pattern my life and conduct

To remember that if I “do today’s work today” I need not be concerned about tomorrow and next month and next year

“ in the summer of 1871, when I was attending the Montreal General Hospital, much worried as to the future, partly about the final examination, partly as to what I should do afterwards, I picked up a volume of Carlyle, and on the page I opened

there was the familiar sentence—‘Our main business is not to see what lies dimly at a distance, but to do what lies clearly at hand’ A commonplace sentiment enough, but it hit and struck and helped, and was the starting-point of a habit that has enabled me to utilize to the full the single talent entrusted to me

“The load of to-morrow, added to that of yesterday, carried to-day makes the strongest falter Shut off the future as tightly as the past No dreams, no visions, no delicious fantasies, no castles in the air, with which, as the old song so truly says, ‘hearts are broken, heads are turned’ To youth, we are told, belongs the future, but the wretched to-morrow that so plagues some of us has no certainty, except through to-day The day of a man’s salvation is now—the life of the present, of to-day, lived earnestly, intently, without a forward-looking thought, is the only insurance for the future Let the limit of your horizon be a twenty-four hour circle On the title page of one of the great books of science, the *Discours de la Methode of Descartes* (1637), is a vignette showing a man digging in a garden with his face towards the earth, on which rays of light are streaming from the heavens, above him is the legend ‘*Fac et Spera*’ ‘Tis a good attitude and a good motto Look heavenward, if you wish, but never to the horizon—that way danger lies Truth is not there, happiness is not there, certainty is not there, but the falsehoods, the frauds, the quackeries, the *ignes fatui* which have deceived each generation—all beckon from the horizon, and lure the men not content to look for the truth and happiness that tumble out at their feet Once while at College climb a mountain-top, and get a general outlook of the land, and make it the occasion perhaps of that careful examination of yourself, that inquisition which Descartes urges every man to hold once in a lifetime—not oftener

“Waste of energy, mental distress, nervous worries dog the steps of a man who is anxious about the future Shut close, then, the great fore and aft bulkheads, and prepare to cultivate the habit of a life of Day-Tight Compartments Do not be discouraged—like every other habit, the acquisition takes time, and the way is one you must find for yourselves I can only give general directions and encouragement, in the hope that while the green years are on your heads, you may have the courage to persist” (“A Way of Life” by William Osler An Address delivered to Yale Students)

It has often been said, “The world bows down to the man who works” It might be said with equal truth that the world is likely to pass with impatience, and perhaps a touch of scorn the man

who constantly stands with outstretched hand and plaintive voice saying "Gimme.

A beautiful tribute to Sir Robert Jones in the *Journal of Bone and Joint Surgery* in 1933 vol 15, pp. 541-543 begins and ends with the following paragraphs

"The kindly word, the cheering smile, the twinkling eye the whole magnetic personality of Sir Robert Jones remains only as a memory. The world's greatest orthopaedic surgeon has completed his life's work quietly as he was born seventy four years ago at Rhyl on the North Wales coast, just as quietly he died in the early days of this year at a little village in Montgomeryshire.

Throughout his career he practised in Liverpool and Liverpool has paid its last and greatest tribute to the honor of one of its citizens. The

ashes of Sir Robert Jones are the first to find a resting place within the walls of the Cathedral. The urn stands on a column of stone, close to the foundation pillar beneath the stained glass window dedicated to 'Service. As long as the walls of that vast cathedral stand, they will shelter all that has died of Robert Jones, as a token and memorial of his service to mankind. In the hearts and minds of those who came within the glow of his presence and who learned humbly to love him his spirit still lives.

It was the spirit of Service that inspired and motivated the lives of Fenger and Osler and Robert Jones and it is that spirit that will bring life's finest rewards to their successors who are just beginning their careers in the profession to which we are proud to be enrolled.

REVIEWS OF NEW BOOKS

A TREATISE on genito-urinary diseases is presented by Pelouze in *Office Urology*¹. He emphasizes the medical aspects of a urologic office practice. The anatomy and physiology of the genito-urinary tract are briefly given as a background for the analysis of the disturbed physiology and pathological lesions.

In this volume a most competent, experienced authority exposes to the reader the secrets and difficulties encountered in a successful urologic practice. Necessities, such as adequate office floor space, cleanliness, and equipment for simple routine laboratory procedure are covered in detail.

The discussion of gonorrhea is priceless. In simple and plain language the diagnosis and the gentle art and science of its treatment are uniquely presented. Adequate reasons for routine office use of Gram's stains are given. The pitfalls in smear diagnosis are likewise emphasized. Gram positive cocci may be mixed with gram negative ones due to variation in size, dye intensities, mutation or fission forms. Uncertainties of identification of cocci by cultures are pointed out. Subculture from liquid medium to solid medium will invariably change the chain formation on smears to clusters. The author states he has reached a point "where he does not know a staphylococcus from a streptococcus in ordinary cultures." In the treatment of gonorrhea the value and shortcomings of sulfanilamide and its derivatives are brought up to date. The fact that many patients remain carriers following sulfanilamide therapy is forcibly brought to the reader's attention. A warning to include a culture for the gonococcus in the criteria of cure in all patients treated with sulfanilamide is added to spare many innocent victims the disease.

The recognition and management of specific and nonspecific prostatitis is most comprehensive. The physician must be thoroughly familiar with the normal to recognize and interpret the abnormal. Not all normal secretions come from normal prostate glands. Repeated examinations will show evidence of infection and not irritation of a normal gland. Seminal vesiculitis is deflated as a common focus or harbinger of infection. Seminal vesiculograms are rarely indicated.

Adequate drainage is given as the primary remedial measure affecting genito-urinary infections. The following points are neatly made: (1) All genito-urinary infections produce pus. (2) In the presence of pus good drainage is essential. (3) All things

equal—the better the drainage, the better is the response. (4) Chronicity is the result of poor drainage. (5) An organ has an inherent tendency to get well unless there is an effective feeder in some poorly draining contiguous organ.

The influence of the mind upon the urinary and sexual function is well presented. Frequency of urination and nocturia may be psychic in origin. Urinary retention may be functional. To search the mind as well as the urinary tract is a safe precaution. Psychogenic sensory symptoms are not imaginary any more than the pain of a true neuritis.

A comprehensive review of this textbook reveals a brief inclusion of all major urologic lesions, diagnostic procedures and treatment, medical, instrumental, and operative. One is strongly impressed with the inseparability of "office urology" and "hospital urology." This volume should prove most helpful and instructive to all who are interested in genito-urinary infections. LEANDER W. RIBA

THE concise and well written volume of 135 pages by Handfield-Jones entitled *Surgery of the Hand*² is an excellent contribution to the subject of hand surgery and emphasizes again how far-reaching and important have been the results of Kanavel's pioneer work on infections and injuries of the hand. In his preface the author acknowledges his indebtedness to Kanavel, and in discussing the subject of infection and injury constantly refers to his teachings. Two-thirds of the volume is devoted to a discussion of infections of the hand and their sequelae, a second section of 23 pages to injuries, and the final section of 21 pages to other surgical lesions.

In reviewing a volume which is so well written and which stresses wisely and forcefully correct surgical principles it may seem unduly critical to select anything for adverse comment and in doing so we would not detract from the commendation that has been expressed. In discussing prevention of infections after injury the author states (p. 7) "Should the hand be dirty—more harm than good can be done by washing. The injured part is immersed in a bath of tincture of iodine for three minutes, the skin edges being separated to give access to the iodine." One would like to substitute for this advice the suggestion that simple soap and water cleansing followed by irrigation with sterile salt solution, if carried out within 2 hours of the time of injury, is an ideal method of transforming a contaminated wound into a clean surgical wound that can be re-

¹OFFICE UROLOGY WITH A SECTION ON CYSTOSCOPY. By P. S. Pelouze, M.D. Philadelphia and London: W. B. Saunders Co. 1940.

paired and closed with safety and with every likelihood of primary healing.

On page 60 on the anastomosis, I believe that immediate suture of the anastomosis is both a safe and dangerous whereas a free tendon should be united at once. Such advice seems to ignore the fact that the result of any tendon suture depends first of all upon securing primary wound healing and without infection. Tendons should be sutured unless the surgeon is convinced that the wound is a clean surgical wound. The fact that infection is likely to be more disastrous if it occurs with a tendon anastomosis does not affect the essential principle involved.

Throughout the volume excellent illustrations have been used which add greatly to its attractive appearance and to clarity of the discussion. Altogether this contribution is an excellent and desirable addition to the literature of surgery of the hand.

STANLEY L. KOCHE.

THE first volume set entitled *Abdominal Operations* by Malngot, containing some 300 pages, would seem to be more properly entitled "Surgical Conditions of the Abdomen" since at least as much space is devoted to discussion of the etiology, pathology, symptoms, and diagnosis as is given to the operations. There are many nicely executed drawings of operative procedures which help clarify the accompanying descriptions.

The first volume covers abdominal incisions, stomach and duodenum, spleen, pancreas, gall bladder and bile ducts. These subjects are fully discussed and many references are made to the current literature, though not always to the most recent contributions. A more critical stand by the author in handling the subject of suture materials and wound closure technique would be thought desirable by many surgeons. The operations of the stomach and duodenum are covered in considerable detail.

Volume considers the liver, appendix, peritoneum, mesentery, omentum, external abdominal hernia, intestines, and postoperative chest conditions. The greatest allotment of space is given to the vermiform appendix in this volume. American contributions to colon surgery are prominently mentioned.

The impression is given of a rather thorough review of the literature by the author, possibly not quite sufficiently critical to help the untrained surgeon and offering little new material for those well trained.

THOMAS C. DOUGLASS.

THE first four chapters of *Diseases of the Urethra and Penis* by McCrea are devoted to the anatomy, anomalies and congenital malformations. The discussion of gonorrhea is brief. For its treat-

ment, four-foot Janet urethral grand lavages, 1 cc daily and urethral instillations of 3 to 5 per cent protargol solution four times daily are recommended. Definitive value was assigned to the use of vaccines in acute Neisserian infections. The salphonamide group is mentioned, but the author feels it is too early to say whether or not the results claimed are unduly optimistic. In a series of 2770 patients with gonococcal urethritis treated at St. Luke's Hospital, Manchester complicating epididymitis was noted in 53 patients, or 7.7 per cent. The treatment of acute epididymitis is given as either palliative or operative. A word on gonorrheal arthritis is included.

The subject of urethral strictures is well covered. Classification may be made according to their response to treatment. Surgical treatment of urethral strictures, including their resection, is illustrated in detail, and the treatment pitfalls are emphasized. The discussion of penile and urethral tumors and foreign bodies is adequate. There are many interesting photographs and a few colored drawings.

This volume sums up the bibliography and opinions of many foreign writers on diseases of the penis and urethra, thereby lending itself as a handy reference on these subjects.

LEONARD W. RICE.

THE volume *L. Emmett Holt, Pioneer of Children's Century* is of distinct value in the different ways first and most important perhaps, as a historical outline of the early history and growth of pediatrics as a medical specialty in this country, and second, as the biography of a late Victorian physician in New York City. The authors have produced a readable and interesting work from these points of view. Because the subject matter is not particularly dramatic, it would probably interest a limited number of people. However, anyone interested in the history of medicine or in the medical life and manners of this period will enjoy reading it. I should imagine, however, that the sale of *The Care and Feeding of Children* will exceed and outlive its author's biography. A well tabulated index is included.

C. ANDERSON ALDRICH.

THE book *Hydrocephalus* by Marburg is commonly confusing. One can excuse sentences the structures of which are more German than English even such humorous but lumpy terms as "hydrocephalus ocellus anterior of Guttman," "subependymal luxuriantia," and "transmineralization" can be managed by a patient reader. However one gains the impression that the opinions expressed in this book have been formulated more through a critique of the work of others than by personal experience and observation by the author. One feels that possibly the author has a completely clear under-

SYNOVIAL SARCOMAS IN JOINTS, BURSAE, AND TENDON SHEATHS

A Clinical and Pathological Study of Sixteen Cases

DOMINIC A. DE SANTO, M.D., ROBERT TENNANT, M.D., and PAUL D. ROSAHN, M.D.,
New York, New York

CLINICOPATHOLOGICAL knowledge of sarcomatous tumors in general has lagged somewhat behind similar knowledge of epithelial tumors. The former show such marked histological variability that classification is frequently an expression of individual opinion. While in many instances, the classification of sarcomas may seem to represent an academic nicety, nevertheless it is highly essential if one is to draw accurate statistical conclusions and avoid misinformation as to the efficacy of any form of treatment. Progress in the study of mesenchymal tumors, however, is surely being made, and the identification of a synovial sarcoma with specific synovial characteristics represents an achievement in this direction.

Synovial sarcoma would appear to be a rare disease if the reports in the literature are to be regarded as trustworthy. It is our feeling, however, that this rarity is far more apparent than real. Histological recognition of the tumor is often difficult unless certain specific features are demonstrable. Failure in

this regard will relegate the tumor to an improper category. Moreover, clinical recognition is difficult particularly as regards the intra-articular tumors involving the knee joint. Here the disease remains undiagnosed for from 5 to 6 years, and the patients are usually treated for chronic synovitis or for cartilage injuries.

There have been several excellent communications on synovial sarcomas, notably those of Sabrazes and his associates and those of Knox and of Berger. Wagner reported the first case in the American literature. This was studied by Ewing who called it a "fibro-endothelioma" of synovial origin. Coley's paper deals with the clinical features of the disease as they appeared at that time. The older literature is inadequate in that pathological descriptions are so incomplete and end-result studies so poor that conclusions are misleading. Mention should be made, however, of the papers of Stuer, and of Lejars and Rubens-Duval. The former described an "adenosarcoma" of the elbow region identical with our Cases 1 and 2, the latter described with excellent illustrations a similar tumor of the knee joint, and independently called attention to the fact that the tumor in some areas resembled an epithe-

lioma and in other areas a sarcoma. An "epitheliosarcomatous" histological appearance has thus become identified as a striking feature of most synovial sarcomas.

Smith writing in 1927 rediscovered these tumors and coined the designation synovioma to indicate their specific synovial nature and origin. This term unfortunately suggests a benign tumor. Mere synovial localization does not suffice to establish a tumor as a synovioma. Thus a hemangioma or chondroma of the synovial membrane is not a synovioma. The term "synovioma" has found such general acceptance however that it is difficult to displace. We are inclined to favor Berger's suggestion of synoviosarcoma or synovial sarcoma for the malignant tumors of specific synovial origin.

CLINICAL STUDY

The present study of 16 cases of synovial sarcoma was undertaken in a further attempt to study this obscure disease clinically and pathologically.

Gross anatomy. Synovial sarcomas originate in synovial tissue and thus are found in joints, para-articular bursae, and in tendon sheaths. In general they occur in or near a joint and since the relationships of the different synovial tissues are extremely variable and complex, it is often difficult in an individual case to establish the exact site of origin. This difficulty is enhanced when the tumor is of wide extent and of infiltrating character. Moreover the intra-articular synovial membrane is so frequently continuous with that of the para-articular bursae that bursal and intra-articular involvement may be simultaneous or successive.

Anatomically the tumors fall into 3 groups (1) encapsulated—Cases 1, 2, 3, 8, 9, 10 (2) circumscribed—Cases 4, 6, 12, 13, 14, 15, 16 (3) diffuse—Cases 5, 7, 11.

The majority of encapsulated tumors take origin from the synovial membrane of a para-articular bursa and the capsule is formed by the bursal wall. Circumscribed tumors may originate in a bursa or a tendon sheath. Diffuse tumors are classically seen within the knee and show simultaneous or successive involvement of joint, suprapatellar pouch, and

popliteal region. Indeed they may even invade the adjacent bones.

The gross appearance of the tumor is subject to considerable variation. It may be solid fibrous, and homogeneous, essentially like an encapsulated fibrosarcoma. In general however it appears soft, and myxomatous at least in areas. Grossly cystic areas and clefts are occasionally recognized. Yellow brown pigmentation of the tumor with hemosiderin is sometimes observed, similar to that of the benign xanthomatous giant cell tumor (Cases 10, 13 and 14). Focal areas of calcification chondrification and ossification are found more frequently than in other soft tissue sarcomas (Cases 1, 3, 6, 8, 9, 11). Broders encountered calcification in only 11 of 152 cases of soft tissue sarcoma, and Shields Warren, who reviewed 155 cases, did not mention it at all. Moreover it is not unlikely that among fibrosarcomas showing calcification and ossification there may not be some overlooked synovial sarcomas, since the pathological distinction is often impossible without prolonged study.

Location. The location of the tumor in our 16 cases, to which are added 21 authentic cases from the literature is shown in the table. Although the series is small it is impressive in that approximately half of these tumors occur in or about the knee joint.

Site of lesion	Total number of cases	Location		
		Articular	Para-articular	
			Bursa	Tendon
Knee	16			
Elbow			5	
Femur				
Shoulder				
Finger				
Thigh				
not				
Total	37	14	16	7

ETIOLOGICAL FACTORS

The etiological factors to be considered are (1) The rôle of trauma (2) the influence of chronic bursitis or chronic synovitis (3) age incidence (4) sex incidence.

Trauma Trauma was mentioned in 4 cases, in all of which the knee joint or its adjacent bursae was involved. In 3 cases the trauma was severe and direct, whereas in 1, it was indirect. In 1 case careful history elicited the onset of symptoms prior to trauma. Twelve cases gave no history of trauma. It seems most likely that trauma occasionally initiated the onset of symptoms but by no means produced the tumor.

Chronic bursitis or synovitis The progression of an inflammatory hyperplasia into a neoplasm has often been recorded. One of our cases (Case 3) occurred in an olecranon bursa with a 10 year pre-operative history and strongly suggests that a previous bursitis may occasionally predispose to the development of a synovial sarcoma. The frequent localization of the knee tumors in the popliteal space where bursae are so prevalent, and the co-existence in both the benign bursa and the malignant tumors of blood pigment, bone, and cartilage, arouses further suspicion that, in rare instances, a chronic bursitis may predispose to the onset of a synovial sarcoma. The long duration of symptoms in the intra-articular knee joint cases also raises the query as to whether these were primarily, or became secondarily, malignant.

Age at onset of symptoms The age incidence is predominantly between the twentieth and fiftieth year with the average at 34 years. In Berger's composite series of 24 cases from which we have excluded 3 cases¹, the average age was 35.4 years. The age incidence is notably younger than that for fascial sarcoma or fibrosarcoma of bone. In the former Broders finds an average of 43.2 years. In Warren's group of fibrosarcomas the average age is about 50 years. Smith, however, encountered an undoubted synovial sarcoma in a 7 year old girl. The tumor was located in the right knee and symptoms of internal derangement had been present for about 3 years.

Sex Synovial sarcoma occurs more frequently in the male sex—11 of our 16 cases and 13 of Berger's 21 cases. For the combined series the incidence is 24 males and 13 females. This differs but slightly from the sex

incidence of fascial sarcoma as reported by Broders and by Warren.

SYMPTOMS

Clinical symptoms of synovial sarcoma are neither striking nor characteristic. In xanthomatous giant cell tumor of joints and in hemangiomas of the knee joint, the symptoms are frequently of sufficient uniformity to permit of pre-operative diagnosis. An analysis indicates that (1) pain, (2) tumor, (3) joint dysfunction, (4) occasional fluid swelling of a joint comprise the chief clinical symptoms.

Pain Pain is not a constant feature being present only in 8 of our 16 cases. Here the duration of pain varied from 9 months to 10 years, and the patients were usually treated for synovitis. In all of the cases involving the knee joint, however, pain was present and the majority of these showed diffuse invasion of joint and para-articular structures. Some cases showed gross implication of a nerve trunk. Pain was absent or inconspicuous in the encapsulated or circumscribed para-articular tumors. Three of the painful cases involving the knee joint were explored and external semilunar cartilages were removed without the nature of the disease being discovered (Cases 2, 4, 11). Indeed, 1 case, Case 7, had two explorations without discovery of tumor. Many tumors were painless, localized, or encapsulated swellings as in Cases 1, 2, 3, 4, 9, 13.

Tumor Tumor was noted by the patient in 10 of 16 cases. The known duration of tumor varied from 1 month to 10 years with the average at 29 months. The location of the tumor undoubtedly influenced its discovery. Superficial tumors, as in the cubital fossa, olecranon, or wrist appeared early. Tumors concealed within the knee joint, popliteal space, or suprapatellar pouch eluded discovery for an average period of 5.6 years.

Dysfunction Dysfunction was present in 10 of 16 cases. It varied from slight restriction of motion to a severe painful flexion contracture, as illustrated in Case 4. Dysfunction was caused either by intra-articular involvement, or by pressure upon the joint structures by an adjacent tumor.

Swelling Fluid swelling occurred in only 2 of the 16 cases. Both cases (11 and 14)

¹ Berger's Case 4 was excluded because of incomplete data, his Case 9 is our Case 10 and Berger's Case 10 we re-examined and found to be a typical xanthomatous giant cell tumor.

showed intra-articular involvement. Centrifugation of the joint fluid and examination for tumor cells was unsuccessfully attempted. Fluid swelling which is quite common in joint xanthoma, would thus appear to be present only in intra-articular synovial sarcoma.

Duration of symptoms The average pre-operative duration of symptoms for the entire series was 36 months with extremes at 1 month and 10 years. The series is too small to permit correlation of the pre-operative duration of symptoms with end results. If those cases showing intra-articular knee involvement are considered separately however the pre-operative duration of symptoms was 5.6 years. Prolonged painful disability in a knee should always be regarded with suspicion.

ROENTGENOGRAPHIC EXAMINATION

X-ray examination was made in 13 cases and in 10 of these, a soft part tumor near a joint was visualized (Cases 1 6 8 9 10, 11 13 14 15, 16). In 4 cases (Cases 1 6 8 9) the tumor showed irregular calcification which facilitated x-ray visualization. In 2 cases (Cases 10 and 11) the tumor was overlooked on first examination but was readily discovered on review of the original films. One case (Case 5) showed increased intra-articular soft part thickening 5 years before the diagnosis of synovial sarcoma was established but this was not regarded with suspicion. Exception must be taken therefore to the statement that x-ray films of synovial sarcoma are usually negative. Closer attention to soft tissue detail will undoubtedly lead to their more frequent discovery. Not unlikely pneumarthrography will further improve x-ray diagnosis. In Cases 5 and 8 extensive destruction of the bones comprising the knee was found without confirmatory x-ray evidence. A more comprehensive review of some of the roentgenographic features of synovial sarcoma are to be found in an article by Raymond Lewin.

TREATMENT AND END-RESULTS

The previous treatment accorded to synovial sarcoma has in our opinion erred by being too conservative. Treatment has generally consisted of local excision followed by delayed

amputation, unless the course of the disease was interrupted by widespread metastases. The frequent small size of the tumor its encapsulation and the long pre-operative duration of symptoms, all obscure the undoubted malignancy and lull the surgeon into an erroneous sense of security which is not warranted by the end-results.

Treatment by local excision In general, treatment of an accessible and resectable tumor by local excision results in prompt recurrence and essential widespread metastases. This statement is based upon an analysis of 13 cases which had undergone primary local excision (Cases 1 to 4 6 and 8 to 15). Of these 13 cases, recurrence was prompt in 10, in an average interval of 8.9 months, necessitating either secondary excision or amputation. One patient, Case 1 is believed to have developed axillary metastases, and 2 patients, Cases 2 and 9 seem well without disease but have been followed for only 14 and 9 months, respectively. One patient, Case 12 however is well 3 years after two excisions in spite of a prompt recurrence. Histologically it seems to be a less malignant variety of the tumor.

Treatment by delayed amputation In 7 cases (Cases 5 7 8 10 11 12 and 14) patients were treated by delayed amputation. This delay in amputation was usually the result of inability to arrive at a proper diagnosis. Five of these (Cases 8 10 11 12, and 14) had received one or more local excisions followed by prompt recurrence. Six of the 7 cases involved the knee joint and the seventh involved the flexor tendon of the ring finger. There are only 2 survivals of this group, Cases 12 and 14 for 22 months and 1 year respectively.

One conclusion that can be drawn from this small group of cases is that delay in amputation is not permissible in diffuse intra-articular synovial sarcoma.

Value of x-ray therapy It is virtually impossible at this time to evaluate the efficacy of x-ray therapy. Ewing recently stated that in his experience synovial sarcomas responded rather favorably to intensive deep irradiation. In 8 of our cases (Cases 1 4, 8 10, 11 12, 15 16) patients received intensive deep x-ray therapy after local excision. The tumor in

Case 1 has not recurred but patient has developed axillary metastases, in Cases 4, 8, 10, 11, 12, 15, and 16, lesions recurred promptly, Case 10, patient survived 10 years before dying of metastases, however Patients in Cases 8, 10, 11, 15, and 16 did not survive a 3 year period and in Case 4 a prompt local recurrence is scarcely compatible with a long survival

The final chapter in the proper treatment of synovial sarcomas will undoubtedly require revision We believe, however, that for the localized or encapsulated tumors, radical excision followed by intensive irradiation will permit time for pathological examination and gradation of the malignancy of the tumors Whereas all synovial sarcomas are malignant, there can be no doubt that the grade of malignancy follows the general rules for all malignant tumors We believe that the vast majority will require prompt amputation and that the decision as to amputation cannot be too long deferred Pathological distinction from the benign xanthomatous giant cell tumor is important to avoid needless sacrifice of an extremity It may be justifiable in occasional instances to allow time for a single recurrence, but it is never justifiable to await more than one recurrence The general practice of treating soft tissue sarcomas by repeated local excision has certainly not yielded brilliant therapeutic results Broders found from 7 to 45 per cent 5 year cures depending upon the degree of malignancy of the tumors and Warren reported 35 per cent 3 year cures Coley is convinced that the treatment of soft tissue sarcomas by repeated local excision results in more fatalities than would result if early amputation were more frequently resorted to Sabrazes would treat all synovial sarcomas by primary amputation

Treatment of diffuse synovial sarcomas, such as those which involve the knee joint, should be primarily radical at the outset Here the tumor usually involves joint, quadriceps pouch, and popliteal space, and attempts at local removal cannot fail to be inadequate Treatment may thus be summarized

1 Accessible tumors usually encapsulated should be treated by widespread local exci-

sion Pathological examination will permit gradation of the tumor and allow a short period of observation Amputation may be deferred to the time of the first recurrence but never beyond this

2 Inaccessible or unresectable tumors such as those of intra-articular localization should be treated by immediate primary amputation

3 X-ray therapy may retard the growth of some tumors and can be employed after local excisions

HISTOLOGY AND PHYSIOLOGY

Before undertaking a discussion of the histological features of synovial sarcoma it is well to review existent concepts concerning the structural and functional characteristics of normal synovial membrane

In a previous communication, Wilson and one of us reported 9 intra-articular xanthomatous giant cell tumors of synovial origin At this time the conclusion was formed that the tumor arose as a proliferation of synovial lining and subsurface cells in which the evolution of the tumor was frankly histiocytic The plasmodial giant cell, the large foam or xanthoma cell, the mononuclear cells with intracellular hemosiderin pigment, the so called "stroma" cells, and the lining surface cells were all regarded as modifications of a fundamental cell type or histiocyte At this time, the authors were unfamiliar with the histological studies of Francescini and the tissue culture experiments of Vaubel to whom priority is acknowledged for recognizing the histiocytic nature of the synovial membrane

Berger added additional histological evidence of the histiocytic nature of xanthomatous giant cell tumors by demonstrating an abundant delicate argyrophilic reticulum throughout their substance In cutaneous xanthomas which are more properly lipid histiocytomas, there exist, as Senear and Caro have shown, all transitions from a cellular histiocytic tumor without xanthoma cells but with abundant lipid demonstrable by sudan staining to an obvious xanthomatous tumor containing many foam cells We have also demonstrated an abundant arborescent argyrophilic reticulum in these tumors, which these authors did not point out

It seems quite apparent, therefore that in histological study the histiocyte can at present be demonstrated in one or all of the following ways (1) demonstrable lipophagic properties, (2) demonstrable siderophagic properties (3) reticulin production.

In addition the histiocyte possesses an endothelial appearance and tends to be polymorphous.

In the knee joint of the 4 month embryo we have observed a syncytial structure of the entire synovial mesenchyme manifested more prominently by a characteristic reticulum. Thus it may be stated that this histiocytic property of reticulin production in the synovial membrane becomes apparent at an early embryological age. Border cuboidal cells do not appear conspicuous and probably make their appearance at a later date. It cannot be assumed, however that the mere demonstration of reticulin is always synonymous with a histiocytic origin. In rhabdomyosarcoma, for example, reticulin production is sometimes as striking in our material as in so called reticulum cell sarcomas. There is great need for additional clarification of the complex problem of reticulin production in normal tissues and in connective tissue tumors.

Vaubel studied synovia by means of tissue cultures and pointed out peculiarities which distinguished it from ordinary mesenchyme. These were (1) a polymorphism of the cells in cultures with a tendency to produce round spindle, polygonal, and epithelioid cells and (2) a functional characteristic, namely the formation of synovial mucin. Berger reviewed the varying concepts concerning the true nature of the synovial membrane. He has regarded it as an histiocytic tissue related to the reticulo-endothelial system and capable of assuming different functional and histological appearances (1) a truly endothelial lining function played by the border cells, (2) a mucin-forming function, and (3) a histiocytic function—exhibited histologically by lipophagic and siderophagic properties, and by the production of a fine reticulin about the cells.

The classical experiments of Key and others demonstrated the phagocytic and migratory character of the synovial cellular constituents

when foreign materials were introduced into joint and further support the concept of the reticulo-endothelial nature of synovial membrane. In various forms of hemorrhagic synovitis, the siderophagic ability of both border and subsurface synovial cells is strikingly exhibited.

HISTOLOGY OF SYNOVIAL SARCOMA

All or any of the normal characteristics mentioned are varyingly exhibited in the sarcomas of synovial origin. Frequently these features co-exist as subsequent histological descriptions will show. In some cases the evolution of the tumor may be predominantly one sided and overshadow other characteristics. The histological appearance of fibrosarcomas and spindle cell sarcomas of fascial or periosteal origin is more characteristically uniform. Here, as Broders states a small area serves to identify and grade the tumor. For the identification of specific synovial characteristics, however multiple sections and careful differential staining are essential because the development of the tumor may be notoriously heterogeneous.

Endothelial characteristics exhibit themselves within the tumor characteristically as epithelioid gland-like spaces often enclosing mucin, or by reproduction of pavement-like areas of tissue strongly resembling epithelium or again, as neoplastic synovial villi. When these characteristic features are strikingly developed, histiocytic features may be partly suppressed, although with reticulin staining one can generally identify two cell types in the tumor one, having the properties of a reticulum cell and another retaining endothelial or epithelial properties.

Mucin production may be confined to gland-like spaces or may appear as small interstitial accumulations among the endothelial components of the tumor cells. Grossly mucin production makes areas of tumor appear myxomatous or gelatinous.

Histiocytic properties may be exhibited in several ways

1 The tumor may closely resemble a reticulum cell sarcoma and be composed of rounded oval, or reniform nuclei supported by a prominent argyrophilic reticulum. Here and

there one may find a gland-like space although this endothelial expression may be suppressed or limited to occasional microscopic areas

2 The tumor may be a polymorphous sarcoma with giant cells, irregular mononuclear, multinuclear cells, blood pigment again supported by a profuse argyrophilic reticulum, although such a tumor may superficially appear different from this description, it is essentially the same

3 The histiocytic evolution may take the form of sheets of xanthoma cells identical with those found in the benign xanthomatous giant cell tumor (see Case 4)

In general therefore all synovial sarcomas are reticulo-endothelial histiocytic sarcomas with varying degrees of reticulum production and endothelial evolution

Many areas of the tumor may show indifferent fibrosarcomatous characteristics, but careful study of multiple areas will reveal the tell-tale specific characteristics. For this reason any fibrosarcoma or spindle cell sarcoma located in or near a joint is very likely a synovial sarcoma, although proof of its identity must depend upon painstaking pathological investigation

For convenience, the appearance of the various histological expressions of synovial specificity in tumors are summarized in table, "malignant neoplasms"

MALIGNANT NEOPLASMS—SYNOVIAL SARCOMAS (SYNOVIOMAS)

- 1 Reticulo-endothelial characteristics (Cases 1, 2, 3, 4, etc)
 - a Composed of spindle cells (reticulum positive) and pale endothelial cells (reticulum negative)
 The endothelium may appear as
 - a A homogeneous pavement like structure with or without intercellular mucin
 - b Gland like spaces with or without mucin
 - c Papillary villi like structures (malignant synovial villi)
 - d Synovial borders resembling hyperplastic synovial membrane
- 2 Predominantly histiocytic features
 - a Polymorphous giant cell features, intracellular blood pigment (Cases 13 and 14 and areas of 10)
 - b May also contain cartilage (Cases 13 and 14)
 - c May reproduce synovial borders
- 3 Common fibrosarcoma or spindle cell sarcoma features may mask a true synovial sarcoma (Cases 6, areas of 10)

Our observations closely parallel and confirm those previously reported by Berger

However, we have been impressed with the extensive calcification, chondrification, and ossification which so frequently take place as scarcely to be coincidental. Calcification occurred in 6 of the 16 cases and had a predominate influence upon x-ray visualization. The calcium was deposited as small or large deposits in an afibrillar albuminoid interstitial substance not unlike that which forms the preosseous substance of newly formed callus. Calcification was not related to x-ray therapy since it was discovered in each case before therapy was instituted. Two additional cases (Cases 12 and 13) showed large islands of fibrocartilage which led to the diagnosis of "chondromatous giant cell tumor"

Chondrification and ossification are less readily explained. In some instances it seemed to result from metaplasia. We suspect that it is closely related to the mucigenic tendency of synovial mesenchyme. Chemically, mucin is closely related to the ground substance of cartilage. Therefore, the detailed explanation of this complex tissue phenomenon must await further elaboration

MALIGNANCY OF SYNOVIAL SARCOMAS

All synovial sarcomas are malignant but in all probability all are not equally malignant. It would be premature at this time to attempt a histological grading similar to that of Broders for fascial sarcomas. Nevertheless, at the risk of being premature, one may hazard some expression of opinion as to the relative malignancy of the different forms

The least malignant tumors are those showing a high degree of histiocytic differentiation characterized by numerous multinucleated giant cells and pigmented cells, and fibrous areas. These tumors resemble somewhat the xanthomatous giant cell tumor or benign histiocytoma, although foam cells have been less conspicuous. Four of 16 tumors prominently exhibited these characteristics. Two patients showed prompt local recurrence. One such patient treated by two local excisions is well without disease after 3 years. One patient, however (Case 10), showed late metastasis and succumbed.

The most highly malignant forms are probably those tumors composed of numerous,

densely packed round, oval and reniform cells with abundant supporting reticulum. Experience indicates that these recur promptly and metastasize quite promptly to lungs, vertebrae, skull, and internal organs.

The tumors showing prominent endothelial characteristics with gland like spaces, appear to lie intermediate in their malignancy although all are undoubtedly capable of wide spread metastasis.

CASE REPORTS

CASE Synovialoma of right antecubital fossa. E. P. male aged 3 years. Treated by local excision and irradiation. Alive with villary metastases after 14 months.

A tin splitter aged 30, was admitted to the Englewood Hospital on May 3, 1939, for acute appendicitis. He also complained of difficulty in flexing and extending the right elbow joint for the past 6 months, and of a mass in the antecubital region.

Examination revealed that in addition to the signs of acute appendicitis, the patient presented a marked prominence of the anterior surface of the flexor group of muscles, overlying the anterior surface of the elbow joint. Extension was limited to 135 degrees, flexion to 90 degrees. Rotation was unimpaired. An x-ray film of the right elbow joint disclosed a circumscribed soft tissue shadow extending to the humero-ulnar articulation with small foci of calcification. A pre-operative diagnosis of fibrosarcoma was made and on May 9, 1939, a local excision of the tumor was performed.

Pathological report. The specimen consisted of an encapsulated gray mass 4.5 by 3 centimeters with adherent synovial fringes. When sectioned the mass was found to be cystic and within the cyst were soft, gray papillomatous nodules, the largest about 1/4 centimeters in diameter undoubtedly the tumor originated from the synovial membrane either of the joint or from a synovial-lined bursa verifying the joint.

Microscopic sections prepared through the thickened area of the cyst all showed tumor which was highly cellular and exhibited many mitotic figures. There were two cell types in the tumor. One was an endothelial cell with oval, pale nucleus and an indistinct cytoplasm. These cells are arranged in rather compact masses and were supported by an amorphous pink-staining substance which in places was rather abundant and resembled secretion of mucin. The other type of cell was somewhat more elongated, with a darker staining nucleus and was arranged in anastomosing masses. In one area the tumor had a papillomatous appearance reproducing tufts resembling neoplastic villi. Here the surface cells assumed cuboidal character. Hematoxylin stain revealed irregular pink-staining threads and strands which had the staining qualities of mucin. These seemed to be confined to the endothelial areas

of the tumor or about the neoplastic villi. With Laidlaw's reticulum stain the difference between the two cell types was greatly accentuated. Pale, non-staining areas corresponded to the endothelium like cells. The darker staining spindle cells are individually supported by a delicate reticulum. Other areas showed coarse deposits of calcium and true bone and about these areas the tumor assumed the character of collections of gland-like spaces composed of cuboidal cells. These were identical with areas from several other tumors.

Patient refused amputation and as given deep x-ray therapy to elbow and axilla. He was last seen in July, 1940, at which time discrete nodules masses were present in both axillae. Roentgenogram of the chest at this time were negative for metastases.

From a histological standpoint this case is a classical synovial sarcoma identical with Berger's Case 2. Small and large gland-like spaces, though not numerous, were present and papillary neoplastic villi predominated in other areas. Gland-like spaces also appeared lined by cuboidal cells and mucin was produced by the tumor.

Clinically the patient already has shown evidence of extension of the disease.

CASE Encapsulated synovialoma of right cubital region. Probable origin in bursa. Treated by local excision. Alive without evident disease after months.

J. B. aged 63 years. Ten years ago the patient noticed a small mass on the medial aspect of the right elbow joint. This gradually increased in size until 6 months ago when it began to enlarge more rapidly. On examination there was found a soft, almost cystic mass 5 centimeters in diameter at the medial aspect of the right elbow. There was no axillary adenopathy. On August 17, 1939, the tumor was removed by local excision. It did not communicate with the joint, tendon sheath.

The tumor was an encapsulated lobulated mass measuring 6 by 3.5 by 3 centimeters. The capsule as made up of strands of glistening tissue throughout which could be seen projecting gray and yellow nodules. It was soft in consistency and on section showed a homogeneous cut surface of glistening pinkish-white tissue in which whorls of dense tissue could be seen. When the cut surface was spread slightly slit like spaces were seen between the bundles and whorls.

The tumor was enclosed in well defined fibrous capsule which in areas showed microscopic infiltration and replacement. It was composed of cells with pale endothelial nuclei and an indefinite cytoplasm drawn out into elongated spindle processes. The bulk of the collagen as intracellular but areas revealed moderate intercellular collagen. In many areas the collagen was more prominent, revealing itself as definite septa subdividing the tumor into rounded

Fig 1 Case 1 a, Photomicrograph showing general epithelioid character of tumor. Note that there are two types of cells, darker staining reticulin positive and paler staining endothelial cells $\times 80$ b, Photomicrograph of another area of tumor showing amorphous deposits of

calcium to the left and characteristic gland like spaces to the right $\times 25$ c, Characteristic area of tumor, Laidlaw stain. The darker cellular elements are reticulin positive $\times 90$ d, Roentgenogram of tumor showing focal calcification

nodules. In every microscopic field there were present great numbers of rounded, oval, and irregularly shaped gland-like spaces lined by cells which resembled cuboidal epithelium. On superficial examination one would be inclined to diagnose this an "adenosarcoma." The space formation exceeded that encountered in any of the 16 cases of the series. The transition between spindle and cuboidal cells in the tumor was extremely gradual. Other areas near the margin of the growth revealed predominately fibrosarcomatous characteristics, but even here there

were slit-like clefts in the tumor with spindle cells playing the border rôle. Reticulum stains were negative, however.

In July, 1940, eleven months after operation, patient was examined and found to be free of recurrence. There was no clinical evidence of pulmonary metastasis.

This case is histologically similar to Cases 1, 5, 7. It is the classical "adenosarcoma" of Stuer even in its location. Its origin was prob-

Fig. 2. Case 2. a, left, Gross section of tumor. b, Photomicrograph. The histological appearance is both "adenosarcomatous" and fibrosarcomatous. $\times 75$.

ably in a para-articular bursa. Histologically it is composed of dedifferentiated fibrosarcoma like tumor and completely differentiated endothelium-like spaces. Intermediate reticulo-endothelial features appear lacking.

Clinically we believe recurrence or metastasis will undoubtedly occur unless the patient accepts further therapeutic measures.

CASE 3 Synovium of olecranon bursa: treatment by local excision.

C. V. female, aged 50 years, a housewife, was admitted to the second Surgical (Cornell) Division of Bellevue Hospital, in November, 1939, complaining of lump on her left elbow of 9 years duration. In the last 30 days, however, it had grown in size and had become red, inflamed, and tender.

Examination revealed over the posterolateral aspect of the left elbow a large mass 4 by 5 by 6 centimeters which was firm, red, inflamed, and slightly warm. The mass was fluctuant. Its apex Clinical diagnosis was inflamed olecranon bursa.

Patient was treated with wet dressings after which on November 20, 1939, through simple incision, the tumor was exposed and easily dissected free from the overlying skin. It was firmly attached to the underlying joint capsule and triceps fascia. The tumor was irregular, firm, partially fluctuant, and extended over the radial head of the elbow joint.

When pathological study revealed that the tumor was a synovial sarcoma, patient was asked to return for amputation but refused. In May, 1940, she returned with local recurrence at the operative site, which was re-excised.

The original tumor was ovoid in shape and measured $\frac{1}{2}$ by $\frac{1}{2}$ by $\frac{1}{4}$ inches. The surface was

nodular and covered by a thin fibrous capsule. On section the tumor presented nodular fibrous consistency. In the center there was a cystic cavity about $\frac{1}{2}$ inch in diameter.

Sections revealed a thin capsule of lamellated connective tissue which was rather vascular and which varied in thickness at different locations. Continuous with the capsule and filling the center of the tumor mass, was a rather dense cellular overgrowth composed of closely packed cells with nuclei that were rounded, oval, vesicular or reniform, and with prominent nucleoli. The nuclear membrane was sharp and distinct, the nucleus as pale the nucleolus was generally black, but sometimes had a faint pink tint giving it the appearance of an epithelial or endothelial cell. Mitotic figures were fairly numerous, 1 or 2 per high power field. In many locations, there could be seen two general cell types: fasciculi of more elongated spindle-like cells and groups of more polygonal cells with rounded or oval nuclei. There were indefinite transitions between the two cell types.

In places the tumor was relatively acellular and the mass was subdivided by thick bands of calcified and ossified hyaline material which resembled fibrocartilage and connective tissue. There were also more delicate strands of pink staining material surrounded by closely approximated tumor cells which had the appearance of an albuminoid deposit within the tumor. In a rare instance it was possible to identify irregular endothelium-like spaces within the tumor filled with a serous material and blood, and lined directly by cuboidal tumor cells. In a few areas the appearance was characteristic of fibrosarcoma with occasional large plasmoidal giant cells. Mucicarmine stain revealed slender positive threads of mucin among the cells. Reticulum stain disclosed a uniform rich a borecent reticulum surrounding individual and groups of cells.

The tumor is fundamentally a reticulo-sarcoma composed of rounded and elongated elements both of which are reticulum positive. Endothelial evolution is revealed by some well formed gland like spaces, but is less conspicuous than in Cases 1 and 2. Focal areas reveal fibrosarcomatous characteristics. Interstitial mucous production was prominent. Calcification and ossification were also observed.

Clinically without amputation the prognosis is unfavorable.

CASE 4 Synovium of right thigh probable origin in bursa overlying lesser trochanter treated by local excision.

C. C., 26 year old colored housewife was admitted to the Meadowbrook Hospital on the service of Dr. Norman Treves, for tumor of the inner side of the right thigh, of 9 months duration. For the past 3 months, the mass had slowly increased in size and had caused occasional gnawing pain.

Fig 3 Case 3 a, Photograph of drawing of synovial sarcoma involving olecranon bursa, $7/12$ actual size b, Photomicrograph showing characteristic reticulosarcomatous ap

pearance $\times 235$ c, Photomicrograph, reticulosarcomatous area of tumor. Other areas show characteristic gland like spaces $\times 60$

Examination revealed a firm, nontender, tumor mass about the size of an orange beneath the adductor muscles high up on the inner aspect of the thigh. A roentgenogram, January 19, 1940, showed a small mass on the upper end of the femur with a sharply outlined periphery of the same density as the muscle tissue. There was no evidence of bone involvement or of calcification.

A biopsy on January 23, 1940, resulted in a diagnosis of synovial sarcoma, and on February 17, 1940, a radical local excision of the tumor was performed. In spite of deep x-ray therapy the tumor recurred to its original size after a period of 3 months. Further data are not yet available, however, there is no doubt but that this case will terminate with generalized metastases.

Specimen was an encapsulated cystic tumor mass about 8 by 15 centimeters, which on section was friable and showed numerous xanthomatous areas which were revealed as yellow, circumscribed deposits throughout the tumor.

The microscopic features were quite similar to those in Case 1, with the addition that the histiocytic areas of the tumor could be shown undergoing evolution into large masses of xanthoma cells indistinguishable from those ordinarily found in benign xanthomatous giant cell tumor. In some areas the tumor was extremely fibrous and here the histologi-

cal picture was similar to that of benign xanthomatous giant cell tumor, with the additional finding of islands of endothelial cells which assumed a gland-like pattern. With the reticulum stains the distinction between the endothelial and histiocytic components of the tumor were more clearly demonstrated and the evolution of the reticulum elements into foam cells by a progressive lipophagic infiltration could be clearly shown.

Many areas showed a structure quite similar to that of a papillary adenocarcinoma, the papillary appearance reproducing synovial villi lined by cuboidal cells.

This case is most valuable from the histological viewpoint in that it demonstrates the widely varying cellular appearances that the tumor elements can assume. Dark-staining reticulum positive areas, pale endothelial areas, areas resembling papillary adenocarcinoma, and areas resembling benign xanthomatous giant cell tumor were all present. It also illustrates the fundamental histological identity of origin of the benign xanthomatous giant cell tumor which is essentially a benign histiocytoma and the malignant synovial sar-

Fig 4 Case 4 a and b, Photomicrographs. Note the papillary character of the endothelial cells of the tumor reproducing neoplastic synovial villi. Note also the epithelioid sarcomatous character illustrated better in b and the xanthomatous transformation. The xanthomatous cells

may be traced to the darker staining reticulum positive elements of the tumor, confirming their histiocytic nature $\times 75$ c, Another area of same tumor showing complete histiocytic differentiation scarcely distinguishable from that seen in benign xanthomatous giant cell tumor $\times 63$

coma which is essentially a malignant reticulo-endothelial sarcoma from synovial tissue.

CASE 5 Synovialoma of left knee joint and suprapatellar pouch and popliteal space. Terminating, 3 months after amputation, in generalized and pulmonary metastases.

H. S. 3 year old student, was first seen in the Hospital for Repaired and Chipped, June 27, 1932,

complaining of pain in the left knee for 8 months. Shortly before the onset he was hit in the left knee with hockey puck. Pain was aggravated by motion or exercise.

Examination of the tumor was essentially negative except for slight limitation of extension.

A roentgenogram, June 9, 1932. Dr. Raymond Lewis reported revealed "no bony changes and the joint spacing seems normal and symmetrical. There

is a mottled increase in density of the soft tissues of the joint anteriorly below the patella."

A diagnosis of chronic traumatic synovitis was made and patient was treated by physiotherapy and strapping. He left the clinic, however, and consulted various physicians who treated him for arthritis. One year later he was operated upon at another hospital with a diagnosis of dislocated semilunar cartilage. This operation resulted in no improvement of the intense pain. In February, 1937, he presented himself with a large swollen left knee. Roentgenograms were inconclusive. The knee joint was explored and a tumor was encountered in the suprapatellar pouch. On February 9, 1937, an amputation at the junction of the upper and middle thirds of the thigh was performed for synovial sarcoma. Roentgenogram of chest at the time was negative for metastases. After amputation, patient was given 7 injections of Coley's toxin.

On May 25, 1937, a chest x ray film disclosed many metastases scattered through the lungs. He

gradually weakened and died on March 15, 1938.

A fusiform swelling involved the entire region of the knee for about 6 inches above and below the joint. On sagittal section of the amputated extremity there is found a soft area of new-growth which apparently has its origin in the synovial membrane of the knee joint in its posterior aspect, and which extends into the suprapatellar pouch anteriorly and posteriorly for about 2 inches, invading the soft tissues of the popliteal space. It also invades the upper end of the tibia and the lower end of the femur.

Microscopic sections show a tumor composed for the most part of large rounded and blunt spindle cells with pale oval vesicular and reniform nuclei. The cells suggest endothelium in their general appearance and arrangement. The tumor for the most part is diffuse and compact, but in places the arrangement is loose and the tumor reproduces gland-like, irregular spaces filled with mucoid fluid. Elsewhere the cells are slightly elongated and spindle shaped, suggesting spindle cell sarcoma. In a few places it

is possible to trace the tumor to a lining synovial layer of cells. There are areas which show stream-like invasion of joint capsule and ligamentous structures. There is no tendency to reproduce cartilaginous or osteoid elements. A few large collections of typical xanthoma cells are also found. Sections of femoral condyle and upper tibia show replacement by similar areas of tumor. Mucicarmine stains fail to reveal the presence of mucin. With Laidlaw's reticulum stain two cell types can be distinguished. Clear negative areas correspond to the more rounded cells, and numerous positive fine threads of reticulin correspond to the more elongated cells.

Diagnosis. Synovial sarcoma (synovioma).

Histologically. Case 5 is essentially similar to Cases 1, 2, 3, 4. The endothelium-like areas are less numerous but are most typical and correspond to those in the classical descriptions of Stuer and of Lejars and Rubens Duval.

The pre-operative duration of symptoms in this case was 6 years. Pulmonary metastases appeared 3 months after amputation and death intervened 13 months after amputation. In spite of an exploration of the knee joint in 1933 the possibility of synovial sarcoma was not considered. The tumor showed bone invasion of great extent.

CASE 6. Synovioma of left lateral knee, probable origin in bursa of vastus lateralis. Treated by two local excisions. There has been no second recurrence after 5 years.

This patient G. B. was admitted to the Hospital for Ruptured and Crippled on August 26, 1938, complaining of painful mass on the left leg. It states that 3 years ago, while playing baseball, he was

"spiked" on the lateral aspect of his left knee with the shoe of another player. There was slight swelling and pain about the knee, and it was treated by hot applications until the symptoms disappeared. Three months later the pain and swelling recurred. These symptoms gradually increased during the next 8 months and at that time, 8 months after the injury, he consulted a physician. X-ray films were made and he was admitted to another hospital where tumor was excised, involving the semimembranous musculature and leading back to the popliteal space.

Pathological examination described a tumor measuring 5 by 3½ by ½ centimeters, having the consistency of soft bone. On microscopic section, it showed incomplete ossification and calcification imbedded in hyalinized connective tissue. A few osteoblasts were scattered about the osteoid spicules. The final diagnosis was a benign osteoma.

Patient was free of pain for 3 months, after which it recurred, and gradually increased. The mass also recurred, growing slowly during the past year.

Examination revealed a well developed and nourished male of 25 years. There was prominence on the lateral aspect of the left thigh immediately above the knee joint where a well defined tender tumor 7 by 7 centimeters could be felt. It was not attached to the skin but was attached to the deep structures.

X-ray films revealed a soft part tumor lateral to the knee joint, containing irregularly distributed lime. There was no evidence of primary bone or joint involvement. Chest plates were negative.

On September 16, 1938 the patient was again operated upon and tumor was exposed lying within the substance of the vastus lateralis muscle and apparently extending to the capsule of the knee joint. The tumor was excised, including much of the vastus lateralis muscle and some of the capsule.

The specimen was a flat, white, fibrous mass measuring 5 by 3 by ½ inches with some adherent semimembranous muscle composing the edges. On sec-

Fig 8 Case 8 a, left, Roentgenogram of recurrent calcified soft part tumor in popliteal space b, Photomicrograph of area of fibrosis and calcification. Synovial sar-

coma was not suspected until recurrence took place The recurrent tumor is histologically identical with that in Figure 5c. $\times 78$

tion, it was found to be of tough fibrous consistence with some areas appearing soft and fish-like Other areas appeared bony hard in consistence

Large numbers of blocks of this tumor were studied in the attempt to establish the exact type of sarcoma In many areas the tumor presented the typical appearance of common fibrosarcoma, that is to say, it was composed of elongated spindle cells and elongated fibrils in a wavy fascicular arrangement In other areas, the tumor exhibited interstitial deposits of amorphous calcium present as small and large granules which could be seen undergoing various stages of chondrification and ossification About these areas there was a peculiar albuminoid impregnation of the stroma resembling somewhat the preosseous infiltration of osteoid tissue and identical in appearance with areas of Cases 1 and 9

Preparations of the soft fish-like areas showed a tumor of entirely different aspect Here the tumor was composed of a syncytium of cells with pale, oval nuclei with a definite nuclear rim and a prominent nucleolus In some areas the tumor elements could be seen grouped about small blood vessels In a few areas the arrangement of the cells was pseudoglandular and here they could be seen forming gland-like spaces This arrangement was definite, although it could be located only exceptionally

In these highly cellular areas, it was possible to trace the tumor to a definite synovial border, which resembled a hyperplastic rather than a neoplastic synovial membrane The cells along the border were flattened, but beneath the border there were fairly numerous, pale, oval nuclei which were difficult, if not impossible to distinguish from the endothelium-like tumor elements present in the deeper tissues Mucicarmine and reticulum stains of soft cellular areas showed anastomosing mucin threads and a rich fine arborescent reticulum around almost every cell

A diagnosis of synovial sarcoma was made and the patient was advised to have an amputation but refused

A report obtained October, 1939, indicates that the patient is working and apparently in good health It is our belief, however, that, without further treatment, dissemination of the disease is inevitable

The bulk of this tumor resembles a common fibrosarcoma of moderate malignancy (grade 1) Areas of calcification, albuminoid infiltration of the stroma lead to a suspicion of synovial sarcoma Soft areas of tumor sectioned revealed sheets of pale endothelium-like cells, synovial borders, and occasional gland-like spaces as well as intercellular threads of mucin The specificity of the tumor was thereby assured This case closely parallels one quoted by Berger as occurring in Sabrazes' laboratory in which (footnote p 534) the original tumor was identical with that in our Case 1 and Berger's Case 2, and the recurrence was indistinguishable from common fibrosarcoma Calcification and albuminoid impregnation, though not entirely specific features of synovial sarcoma, are helpful in arriving at the diagnosis Areas of reticulo-endothelial evolution although not so well developed as in Cases 1 and 2, are none the less strikingly dissimilar to the fibrosarcomatous areas

CASE 7 Synovioma involving right knee joint, popliteal space, and biceps femoris tendon, treated

Fig. 9. Case 9. a, Roentgenogram of tumor of dist. b, Reticulosarcomatous area. $\times 52$. c, Another area showing calcification of tumor. $\times 52$.

for years as internal derangement of knee joint, later by amputation. Alive with pulmonary metastases after 2½ years.

E. S., a Jewish housewife aged 37 years, was referred to the New Haven Hospital on January 1, 1937. She first noticed pain in the knee in the summer of 1934 and in January 1935 after having wrenched her right knee in an automobile accident the pain had become worse. A diagnosis of rupture of the external semilunar cartilage was made and on January 30, 1935 the joint was explored and the internal semilunar cartilage was removed. In August 1935, she was readmitted to the hospital where she remained until September for correction of flexion contracture by a wedge cast. In January 1936 she was readmitted and a second arthrotoomy performed. A mass of necrotic granulation material was removed from the external posterior aspect of the cartilage and reported as follows:

Pathologically the specimen was received in several small pieces, the largest one measuring 5 by 5 by 1 centimeter. On section these pieces presented homogeneous cartilaginous structure. The microscopic sections showed cells of cartilage type. No evidence of any abnormal pathology could be found. The diagnosis as cartilaginous proliferation.

Röntgenographic examination of the joint in January 1935, was reported negative. Roentgenographic examination in December 1936 showed marked narrowing of the joint space, some moderate proliferation about the margin of the joint, and rather marked bone atrophy. Stereographic examination of the chest for metastases as indeterminate.

Physical examination revealed that "the patient's right knee was held at about 3 to 35 degrees flexion. Motion was extremely difficult to obtain. There was considerable periarthritic thickening. There were two operative scars, one over the lateral and anterior aspect of the joint centering on the joint line, and another overlying the lateral hamstring, above the lateral condyle. About the center of the scar crossing

the joint line there was a extremely sensitive nodule about 5 centimeters in diameter apparently attached to the patella but so sensitive that it could not be satisfactorily palpated for mobility. There was a second movable nodule just above the head of the fibula apparently attached to the deep fascia. The third nodule was found medial to the external hamstring and firmly attached to the deep fascia. There were no enlarged inguinal lymph nodes.

A biopsy of one nodule was made and revealed the presence of sarcoma of synovial origin. On February 8, 1937, mid thigh amputation was performed. Examination of the amputated extremity showed a large tumor mass involving the knee joint and extending into the popliteal space. The patient has been followed since discharge from the hospital. In December 1939, she developed a cough and chest pains. Roentgenogram of the chest revealed extensive pulmonary metastases.

This case like the one reported by Hodgson showed a skin metastasis. The long history of joint disability suggests a primary origin in the joint synovial membrane with outward spread to popliteal space and biceps tendon. In spite of two explorations, the nature of the disease was not recognized. The degenerated tissue removed at second operation was probably necrotic tumor tissue unsuitable for recognition. Clinically the difficulty of diagnosis is similar to that encountered in Cases 2, 10 and 11. Histologically this case is identical with Case 5.

CASE 8. Synovial sarcoma of left knee joint and popliteal space symptoms of 6 years duration. Treated by local excision, deep x-ray therapy and delayed amputation. Death from pulmonary metastases 3½ years after amputation.

Fig 10 Case 10 a, Photograph of drawing, $\frac{1}{4}$ actual size, large intra articular synovial sarcoma of knee joint. b, Photomicrograph of indifferent fibrosarcomatous ap-

pearance, dark areas represent hemosiderin pigmentation $\times 100$ c, Roentgenogram showing large intra articular soft part tumor

L M, a student, aged 24 years, entered the Hospital for Ruptured and Crippled, October 16, 1935, complaining of pain and stiffness in his left knee of 6 years' duration. Six years ago, after falling down a flight of stairs, he injured the knee and following this, he had some swelling. A short time later he was kicked in the left knee and since then he has had pain and discomfort on the lateral aspect, which has grown steadily worse during the past 4 years.

Examination revealed a tender swelling over the lateral aspect of the knee joint. Flexion and extension were limited by about 15 degrees.

Roentgenograms showed a large irregular calcified body lying posterior to the lateral femoral condyle. This body dipped medially and forward into the intercondyloid notch. At the front of the joint opposite this projection there appeared a good sized oval body with an irregularly calcified periphery and a clear central area.

A clinical diagnosis was made of "calcified popliteal cyst," and on November 4, 1935, the mass was exposed through an incision over the outer side of the left knee. The outer portion of the gastrocnemius was cut and the popliteal space was exposed. From this area, the mass was found to extend forward into the posterior aspect of the knee joint.

The specimen was an encapsulated fibrous mass roughly ovoid in shape, measuring 3 by 2 by 2 inches. Adherent to the capsule there were some loose tags of fibrous tissue. On cross section it was found to be fibrous with nodular areas of cartilaginous and osseous consistency.

Microscopic examination at this time disclosed a fibrocellular tumor scattered throughout which there

were numerous amorphous deposits of calcium, many of which could be seen undergoing metaplasia into cartilage and bone. The stroma in places, was extremely hyaline and fibrous and throughout it were scattered pale oval nuclei which were interpreted as being chondroblasts because they were found lying in a medium resembling fibrocartilage. In addition, there was impregnation of the stroma by a hyaline albuminoid material which could not be positively identified, but which resembled pre-osseous infiltration of fibrous callus. Histologically, this was identical with that found in Cases 1 and 6. In some areas, the aspect was myxomatous being composed of a loose meshwork of stellate cells in delicate fibrils. In other areas, the aspect was fibrocellular, being composed of elongated spindle cells in a collagen-like stroma throughout which were scattered granules of intracellular and extracellular hemosiderin pigment. At that time the possibility of malignancy was not seriously entertained, and the mass was considered to be a calcified popliteal bursa.

Eleven months later, in October, 1936, he complained of a recurrence of his symptoms. Roentgenograms taken at this time revealed an oval soft tissue mass at the back of the joint, with some irregular, scattered, surrounding calcification. The mass seemed to be outside the joint.

Because of the recurrence, the original slides were reviewed. It was then thought that they represented some unusual form of synovial sarcoma. Patient was given deep x-ray therapy without improvement and after 6 months, amputation was advised.

Shortly thereafter he consulted a surgeon in Boston, who excised the recurrence which was found to

be frankly malignant and proposed amputation which the patient accepted.

Amputation of the left leg at the mid thigh was performed at the Massachusetts General Hospital, February 3, 1937. The pathological report is furnished by Dr. Tracy Mallory.

February 3, 1937

B 31 1434

Diagnoses Myxoiditis ossificans

Sarcoma (type undetermined, (?) synovio-sarcoma).

Femur Gross. A left leg amputated at the mid thigh. The knee is markedly limited in motion owing to a large tumor mass of bony consistency which fills the popliteal space and extends over the lateral surface of the joint and the lower end of the femur. Overlying the tumor is a crescentic healed operative incision 6 centimeters in length. This lies approximately in the center of a circular area of erythema and tanning due to recent radiotherapy. After turning back skin flaps and careful dissection, a large tumor mass is finally dissected free. Though an apparent plane of cleavage between the tumor and the joint capsule is found, further investigation shows that the posterior portion of the joint capsule is diffusely infiltrated with tumor and measures 2 centimeters in thickness. The lower border of the tumor is fairly well delimited. It extends beyond the joint and thumb-like projection of soft tumor extends down almost to the head of the fibula. The upper margin is impossible to determine, the tumor infiltrating fibrosed atrophied muscles very widely. A fasciculus of muscle fibers about 1 centimeter in diameter extends upward within 5 centimeters of the line of amputation which is white, partly fibrous, partly gelatinous, and contains granules of calcium. On section the central part of the tumor consists of cyst-like cells to 3 centimeters in diameter of calcified material, apparently bone, each of which encloses a central mass of pearly myxomatous tissue readily expressed by slight pressure. The peripheral parts of tumor show an intermixture of white fibrous tissue with the myxomatous material and only rare gritty granules. A occasional area shows frank "fish-flesh" character over an extent of 1 to 2 cubic centimeters.

Microscopic. The appearance of this tumor is as unusual as the gross. The tumor proper consists of infiltrating strands and masses of very uniform small cells with oval nuclei and scant neutrophilic cytoplasm which is occasionally drawn out into short spindle. There is tendency to fascicular grouping and also to bone formation. Practically no collagen is present between the tumor cells except in the immediate neighborhood of blood vessels and capillaries, and it is improbable that the tumor cells are producing the fibrils re-demonstrated with phosphotungstic acid hematoxylin. Despite the extreme cellularity, mitotic figures are astonishingly infrequent. The tumor is invading fibrous tissue and muscle bundles. Scattered irregularly through it are bony islands, occasionally with trabecular architecture. Many appear inactive but others are bordered

by osteoclasts and osteoblasts and show both lacunar resorption and also osteoid borders. The cartilage also both sharply circumscribed islands of inactive hyaline cartilage and no transitions from cartilage through mucinous tissue to ordinary fibrous tissue. No relation whatever between the bone and cartilage formation and the tumor cell can be made out. The appearances suggest an old focus of myxoiditis ossificans invaded by a new and entirely independent malignant tumor. The nature of this new malignant tumor is by no means clear. Neurogenic fibrosarcoma, endothelioma, and synovio-sarcoma are possibilities. In spite of the absence of epithelium like cells, the latter seems the most probable. It also offers the worst prognosis.

In February 1939, ray films showed definite pulmonary metastases. The patient died September 4, 1939, of pulmonary and generalized metastases. No autopsy was permitted.

Clinically the pre-operative duration of symptoms was 6 years. The interval from onset to death was 10 years. Death occurred 2 1/2 years after amputation and approximately 4 years after first local excision.

A comparison of the tumor with a previous case (Case 5), shows essentially the same round and spindle cell characteristics. Reticulum staining of the old blocks was unsatisfactory due to the age of the material. However, it was impossible to identify gland-like grouping of the cells. The identity with the previous case and other cases together with the localization and clinical course leave no doubt that this is a true example of synovial sarcoma. The calcification, chondrification, ossification and albuminoid infiltration are identical with Cases 1 and 6. The histological identity of the tumor cells with that of Case 5 is further proof of the synovial origin of the tumor.

CASE 9. Synovio-sarcoma of left wrist region, treated by local excision. No recurrence within 9 months.

A. S., housewife aged 34 years, complained of slowly progressive swelling of the anterior surface of the left wrist of 6 years duration. There was no history of pain or trauma.

Examination disclosed a swelling of the anterior and dorsal surfaces of the left wrist overlying the distal end of the radius and ulna.

An x-ray film on March 2, 1939, showed a sharply defined rounded soft tissue tumor mass situated between the radius and ulna. This started just above the lower radio-ulnar articulation and extended up the forearm for a distance of about 4 centimeters. It bulged both anteriorly and posteriorly and it contained a rather irregular deposition of bone. There appeared to be a certain amount of pressure atrophy of the lower ulnar shaft.

X-ray diagnosis Probably synovioma

The patient was advised to enter the hospital for excision, but rejected this advice. She did, however, enter another hospital on March 30, 1930, where the tumor was excised.

The specimen consisted of a circumscribed tumor mass occupying a volume of about 4 centimeters in diameter. On section some areas of this tissue were found to be soft, and presented a homogeneous gray, waxy appearance. Other portions of the tissue contained small spicules of bone. In the main the tumor was composed of a homogeneous gray, waxy appearing tissue with occasional soft necrotic appearing areas.

One of the slides of the microscopic sections showed a densely cellular overgrowth of blunt spindle cells with somewhat rounded nuclei and poorly visible cytoplasm. The cells were compactly arranged somewhat in the manner of epithelial cells, and here and there one noted a mitotic figure among the nuclei. In places the arrangement was whorl like, elsewhere there were areas in which the cells were loosely arranged. In these areas the cells were frequently vacuolated and presented a pseudomyxomatous appearance. In addition, there was a tendency to form slit like spaces with an endothelial lining, and finally, in other areas the structure was highly fibrous, the cells assuming an elongated spindle appearance which resembled that seen in fibrosarcoma. Here the stroma was abundant, and the cells were not numerous, and there was considerable calcium deposition—the calcium appearing as coarse fragments. One small area shows actual bone formation. In general, the tumor exhibited a varied histological appearance and ranged in its appearance from a fibrosarcoma to areas which resembled a reticulum cell sarcoma.

Examination and x-ray film of the wrist in November, 1939, showed no recurrence of the disease.

CASE 10 Synovioma of right knee joint. Treated by repeated local excision, deep x-ray therapy, and delayed amputation. Death 10 years after amputation, of pulmonary metastases. This case was reported in detail by Dr. Lewis C. Wagner and represents the first synovial sarcoma to be reported in the American literature. Follow-up data not then available are now furnished.

H. N., a 35 year old musician, with an irrelevant family and past history, without any apparent cause, began to complain about 10 years ago of pain in the right knee. It was treated with the usual rheumatic treatment by the family physician but with no improvement. In the summer of 1923 he consulted a surgeon and the limb was immobilized in plaster without relief. The patient entered the hospital in October, 1923. Examination showed him to be in good health but he was walking with a slight limp, although the functions of the right knee were not impaired. There was a slight fullness under the right patella tendon. He brought a report of x-ray findings, which were normal. The case was thought to be one of chronic synovitis, and was treated conservatively with cautery and strapping. He did not

improve but, rather, the pain became worse. In January, 1924, an x-ray picture was taken, which showed a mass behind the patella tendon that was thought to be hypertrophied synovial tissue. A definite tumor was not considered but on looking back, it was easily recognized. On February 13, 1924, the patella was split and the knee joint exposed. A solid tumor covered by a synovial veil lay in the knee joint. It was attached to the outer antero-inferior border of the capsule by a small attachment. The tumor measured 7 by 5 by 3 centimeters, was elliptical in shape, and surrounded by a definite capsule.

The patient was free from pain for 1 year when the tumor reappeared on the lateral surface of the knee. An extensive resection of the capsule of the joint was done and the patient was again free from symptoms after the second operation. He received extensive x-ray therapy and a thorough course of Coley's toxin. In 1926 the symptoms and signs reappeared. The tumor had invaded the upper end of the tibia, under the patella tendon. Resection was unsatisfactory at the third operation and 2 weeks later a mid thigh amputation was done.

Examination March, 1930, showed the patient well and free from recurrences or metastases. In 1936, the patient succumbed from pulmonary metastases.

Through the courtesy of Dr. Francis Carter Wood, we were permitted to re-examine a slide which for the most part resembled a common fibrosarcoma. This tumor represents a dedifferentiated synovioma showing predominant fibrosarcomatous characteristics. On the authority of Drs. Ewing and Wood who examined many sections removed at the time of operation, it is included as an undoubted synovioma. Many areas show coarse clusters of intracellular hemosiderin pigment. Multiple sections and special stains could not be employed because the operative material was no longer available.

CASE 11 Synovioma of left knee joint and suprapatellar pouch, treated by two local excisions and delayed amputation. Death from pulmonary metastases.

R. L., a white Hebrew male, aged 25 years, was first seen in the New Haven Hospital in July, 1935, when he complained of pain and swelling in his left knee which he said developed following a baseball game. The patient had a history extending 6 or 8 years prior to this admission, when he noted that flexing the knee resulted in pain which could be eased by extending the leg. In the summer of 1934 the knee suddenly became swollen. No definite diagnosis was made and physiotherapy was instituted without improvement.

Throughout the summer of 1935 the patient continued to suffer pain and swelling. On this admission, roentgenograms were taken but no definite diagnosis was made. Upon review of these original films a definite suprapatellar tumor could be seen. After several days in the hospital the swelling gradually subsided and he was discharged to the ortho-

be frankly malignant and proposed amputation, which this patient accepted.

Amputation of the left leg at the mid thigh was performed at the Massachusetts General Hospital, February 3, 1937. The pathological report is furnished by Dr. Tracy Mallory.

February 13, 1937.

B M 1434

Diagnosis: Myositis ossificans.

Sarcoma, type undetermined (?) synovium.

"Femur Gross. A left leg amputated at the mid thigh. The knee is markedly limited in motion owing to a large tumor mass of bony consistency which fills the popliteal space and extends over the lateral surface of the joint and the lower end of the femur. Overlying the tumor is a crescentic healed operative incision 6 centimeters in length. This lies superficially in the center of a circular area of erythema and tanning due to recent radiotherapy. After turning back skin flaps and careful dissection, large tumor mass is finally dissected free. Though an apparent plane of cleavage between the tumor and the joint capsule is found, further investigation shows that the posterior portion of the joint capsule is diffusely infiltrated with tumor and measures centimeter thickness. The lower border of the tumor is fully well delimited. It extends beyond the joint and a thumb-like projection of soft tumor extends down almost to the head of the fibula. The upper margin is impossible to determine the tumor infiltrating fibrous trophic muscles very widely. A fasciculus of muscle fibers about centimeter in diameter extends upward to within 1.5 centimeters of the line of amputation which is white, partly fibrous partly gelatinous, and contains granules of calcium. On section the central part of the tumor consists of cyst-like cells at 1.5 centimeters in diameter of calcified material, apparently bone, each of which encloses central mass of poorly myxomatous tissue readily expressed by slight pressure. The peripheral parts of tumor show an intermixture of bony fibrous tissue with the myxomatous material and only rare, gritty granules. An occasional area shows a frank fish flesh character over extent of 1.5 cubic centimeters.

Microscopic. The appearance of this tumor is as unusual as the gross. The tumor proper consists of infiltrating strands and masses of very uniform small cells with oval nuclei and a scant neutrophilic cytoplasm which is occasionally drawn out into short spindle. There is a tendency to fascicular grouping and also to whorl formation. Practically no collagen is present between the tumor cells except in the immediate neighborhood of blood vessels and capillaries, and it is improbable that the tumor cells are producing it. No fibrils are demonstrated with phosphotungstic acid hematoxylin. Despite the extreme cellularity, mitotic figures are astonishingly infrequent. The tumor is invading fibrous tissue and muscle bundles. Scattered irregularly throughout are bony islands, occasionally with a trabecular architecture. Many appear inactive but others are bordered

by osteoclasts and osteoblasts and show both lacunar resorption and also osteoid borders. The cartilage shows both sharply circumscribed islands of inactive hyaline cartilage and no transitions from cartilage through mucous tissue to ordinary fibrous tissue. No relation whatever between the bone and cartilage formation and the tumor cells can be made out. The appearances suggest a old focus of myositis ossificans invaded by a new and entirely independent malignant tumor. The nature of this new malignant tumor is by no means clear. Neurogenic fibrosarcoma, endothelioma, and synovium are possibilities. In spite of the absence of epithelium like cells, the latter seems the most probable. It also offers the best prognosis.

In February 1939, ray films showed definite pulmonary metastases. The patient died September 4, 1939, of pulmonary and generalized metastases. No autopsy was permitted.

Clinically the pre-operative duration of symptoms was 6 years. The interval from onset to death was 10 years. Death occurred 3½ years after amputation and approximately 4 years after first local excision.

A comparison of the tumor with a previous case, Case 5 shows essentially the same round and spindle cell characteristics. Reticulum staining of the old blocks was unsatisfactory due to the age of the material. However it was impossible to identify gland-like grouping of the cells. The identity with the previous case and other cases together with the localization and clinical course leave no doubt that this is a true example of synovial sarcoma. The calcification, chondrification ossification, and albuminoid infiltration are identical with Cases 1 and 6. The histological identity of the tumor cells with that of Case 5 is further proof of the synovial origin of the tumor.

CASE 2. Synovium of left wrist resected, treated by local excision. No recurrence thus 9 months.

A. S., housewife, aged 34 years, complained of slowly progressive swelling of the anterior surface of the left wrist of 6 years duration. There was no history of pain or trauma.

Examination disclosed swelling of the anterior and dorsal surfaces of the left wrist overlying the distal end of the radius and ulna.

An x-ray film on March 8, 1939, showed quite sharply defined rounded soft tissue tumor mass situated between the radius and ulna. This started just above the lower radio-ulnar articulation and extended up the forearm for a distance of about 4 centimeters. It bulged both anteriorly and posteriorly and it contained rather irregular deposition of lime. There appeared to be certain amount of pressure atrophy of the lower ulnar shaft.

Fig 11 Case 11 b, Photomicrograph of a representative area of tumor showing histiocytic evolution, not unlike benign tumors of tendon sheath origin $\times 68$ c, A metas-

tasis of the tumor in a popliteal lymph node $\times 68$ d, An area of recurrent tumor illustrating its dedifferentiated fibrosarcomatous character $\times 68$ Consult Figure 6b

several layers deep in a somewhat palisading fashion. Several popliteal lymph nodes are replaced almost entirely by tumor tissue. Here the tumor has an epithelial character. Strands and masses of small polyhedral and spindle (almost column-shaped) cells are arranged in a delicate connective tissue stroma. Again slit-like spaces lined by several layers of these cells are occasionally seen and in some places there is a suggestive papillary arrangement of the cells. The tumor in this specimen appears less well differentiated than in the first two, but still maintains the characteristic features. The rate of proliferation is also enhanced as indicated by the increased numbers of mitoses.

Clinically, this case illustrates the long preoperative course of the intra-articular synovial sarcomas. Pathologically many areas resembled the "giant cell" tumors of the tendon sheath type similar to that in Cases 12 and 13. A number of pathologists reviewed the slides on this case and regarded it as a benign giant cell tumor. On the basis of areas exhibiting reticulo-endothelial characteristics similar to that of previous cases it was regarded as malignant.

CASE 12 Synovium of superficial flexor tendon of fourth right finger treated by local excision, deep x-ray therapy, and delayed amputation.

E. S., a 32 year old housewife, noticed, in August, 1937, that the ring finger of her right hand was becoming stiff. This gradually progressed until it became painful to move the finger. About the middle of September, 1937, she noticed a slight swelling over this tendon which slowly increased in size. In October, 1937, she consulted a physician, who diagnosed an early Dupuytren's contracture, and pre-

scribed short wave diathermy. In February, 1938, the small tumor was excised and submitted for histological examination. The histological diagnosis was "synovium." Since that time she has received 22 x-ray and 2 radium treatments.

On examination, the ring finger of the right hand showed an x-ray dermatitis with some sloughing and ulceration. There was little function of the finger and an ulceration over the palmar aspect of the right ring finger at the region of the proximal metacarpophalangeal joint.

Examination of the first tumor showed that it was composed of polyhedral and polygonal cells bearing a striking resemblance to epithelium. The cells were present in compact masses which were generally enclosed in delicate trabeculae of connective tissue. The nuclei were pale, oval, or vesicular. The nucleolus was prominent. Mitotic figures were not observed. In other areas the tumor cells appeared elongated, spindle in character, and assumed the character of tumor fibroblasts. The cytoplasmic boundary was distinct and the cytoplasm was pale, sometimes vacuolated, sometimes translucent. There was no resemblance to xanthoma and giant cell tumor. Some areas resembled the tumor reported by Black, but it was impossible to use differential staining methods in the study of this tumor.

Amputation of the right hand and middle third of the right forearm was performed by Dr. Bradley L. Coley on May 10, 1938.

The specimen was a right hand and forearm amputated through the distal third of the forearm. On the palmar surface between the fourth and fifth fingers, there was an irregular ulceration about 2 millimeters in depth. On sagittal section through this area there was found an irregular zone of white tissue resembling tumor tissue, which implicated the tendons and extended down to the metacarpal joint of the fourth finger.

Fig. Case 11. a, Original roentgenogram showing tumor in suprapatellar pouch, overlooked at time of first examination.

pedic dispensary. The diagnosis at that time was considered to be traumatic arthritis with possible ruptured medial meniscus. Finally in March, 1936, he was advised to come into the hospital for operation.

Physical examination of the left knee revealed a slight fluid swelling of the joint. In the suprapatellar region a hard freely movable mass about 5 centimeters in diameter could be palpated. There was no limitation of motion except on flexion, and this was painful to 90 degrees. Some atrophy of the left thigh was evident.

On March 23 a tumor of the left quadriceps pouch was excised.

The patient was discharged April 7 1936 on crutches. On July 30, 1937 a roentgenogram of the knee revealed recurrent tumor of the quadriceps pouch. The patient was seen subsequently in Baltimore where he was reoperated upon in October 1937. At that time tumor tissue was removed from the suprapatellar and popliteal regions.

The patient subsequently returned to New Haven with several draining sinuses and with evidences of recurrent tumor. A course of deep ray therapy delivered through three ports, medial, lateral, and posterior about the left knee with 1500 roentgen units through each port, was given without improvement. In February 1938, an amputation of the leg was performed.

The patient died at home on December 7 1938, of pulmonary and generalized metastases.

The specimen removed March 23 1936, is a diamond shaped mass of firm pink gray tissue which measures 7 by 5 by 2.5 centimeters. The external surface is irregular except on one side where it appeared smooth and shiny. The cut surface is composed of whorls of dense gray hit tissue.

Microscopic sections show the mass to be composed of hyalinized connective tissue stroma embedded in which, in a haphazard fashion, are masses and strands of typical cells. These vary from spindle to polyhedral in shape and have ill defined cell outlines. The predominant cell is polyhedral in shape with small amount of pink staining cytoplasm and vesicular nuclei. Moderate numbers of these cells are in mitotic division. In many places the cells are arranged about slit-like lumina with layer of these cells lining the lumen. In other places the cells are arranged about spaces lined by flattened endothelial cells which appear to be blood vessels. Scattered throughout the section in many of the masses of cells are occasional multinucleated giant cells. One edge of this section has smooth, undulating synovial border which is lined by flattened layer of cells. Subjacent to this surface are masses of polyhedrally shaped tumor cells. This apparently represents the region of the tumor in contact with the suprapatellar pouch.

Histological sections of the recurrent tumor removed from the knee joint in October, 1937 showed structure similar to that of the original tumor.

The specimen removed February 1938, is the amputated leg which has previously been dissected at another hospital. The soft tissue has been removed from the bony framework. In the area over the patella, there are two longitudinal healed scars and in the popliteal space there is another scar which is incompletely healed. In its central portion a sinus communicates with the joint space. The articular surfaces of the joint are almost completely destroyed and have a dull, granular, mottled yellow and red appearance. In the popliteal space are a few somewhat irregular but fairly discrete nodules of mottled gray yellow tumor tissue. Some of these appear to be lymph nodes which are invaded by tumor.

Microscopic section through the sinus tract shows the surface covered by exudate of polymorphous clear leucocytes beneath which there is a mass of granulation tissue infiltrated with lymphocytes, large mononuclear phagocytes, plasma cells, and polymorphonuclear leucocytes. The articular surfaces of the joint are destroyed and involved by this inflammatory process which extends into the underlying bone. There is no tumor in the joint but adjacent to the sinus tract are several nodules of tumor which infiltrate the connective tissue. The tumor is made up of spindle and polyhedral cells which are arranged in masses and strands throughout connective tissue stroma. The cell is variable in size and are basophilic staining. Numerous cells are in mitosis. Only occasionally do masses of these cells line up about slit like spaces where they are arranged

Fig 13 Case 13 a, Photograph of drawing of specimen, $\frac{1}{2}$ actual size. Note the clefts and the areas of pigmentation. b, Roentgenogram of original tumor in popliteal space. c, Photomicrograph of a representative area of tumor illustrating synovial border. Note the multinucleated giant cells and the coarse deposits of hemosiderin to the right. $\times 65$.

and posterior aspects of the left popliteal space, about $3\frac{1}{2}$ by $1\frac{1}{2}$ inches.

Through a vertical curved incision with the convexity toward the inner side, a tumor was exposed deep in the popliteal space. It was adherent to overlying muscles and tendons, and firmly adherent to the capsule. In removing the tumor it was necessary to remove a portion of the posterior capsule.

Pathological report. The tumor is circumscribed but does not have a distinct capsule. It measures 5 by 5 by 2 centimeters. Some loose tags of fibrous tissue are attached to the surface. On section the tumor cuts with a fibrous consistence and shows one fairly large cystic area about 1 centimeter in diameter. Scattered over the cut surface are firm, yellow, ground concentric nodules which have the consistence of cartilage. The intervening stroma is tinted in various shades from yellow to brown, the pigmentation being similar to that seen in xanthomatous giant cell tumor.

Because of the previous diagnosis of xanthomatous giant cell tumor, this tumor was studied by multiple section through a great many areas. The periphery of the tumor appeared largely encapsulated although the capsule was not complete. On superficial examination, there was found a striking dissemination of multiple deposits of intracellular hemosiderin pigment similar to that seen in xanthoma. Vast areas of the tumor presented a fibrocellular aspect, the cells being rounded, oval, blunt spindle, and irregularly shaped with oval and reniform nuclei. The arrangement of the cells was syncytial and this was better demonstrated by reticulum stains which showed both a fine and a coarse arborescent reticulum supporting the majority of the cells. In many of the areas, the stroma cells could be seen differentiating into multinucleated giant cells containing from 2 to 20 nuclei. In some fields giant cells were particularly numerous. Mitotic figures were fairly numerous about two per high power field. In many areas corresponding to the macroscopic concentric nodules, the stroma could be seen differenti-

ating into fibrocartilage. With both hematoxylin and eosin and Sudan III stains, it was not possible to demonstrate lipid in the tumor. Along one edge of the tumor was a well defined synovial border probably that of the semimembranosus tendon. This border showed reduplication of the synovial border cells and multiplication of the subsurface cells with areas of blood pigment similar to hemorrhagic villous synovitis as described in the knee joint.

Throughout the main tumor mass were numerous synovial spaces lined by from one to three rows of polygonal and flattened cells, and these spaces contain a metachromatic mucoid substance.

This tumor represents a form of synovial sarcoma histologically closely related to the xanthomatous giant cell tumor. It has been referred to as the "tendon sheath" type. It differs from xanthomatous giant cell tumor in the presence of typical synovial spaces, the presence of circumscribed areas of fibrocartilage, and the rarity or absence of demonstrable xanthoma cells in the recurrence. No exception is taken, however, to the report of xanthoma cells being present in the original tumor. While the presence of foam cells is a striking feature of xanthomatous tumors, histiocytic tumors are frequently found with little or no demonstrable lipid. Berger in his Case 5 has reported what he regards as the first example of a malignant transformation of a xanthoma giant cell tumor in a white man 50 years of age, located in the anterior aspect of left thigh. This is identical with Berger's Case 5 showing synovial borders filled with blood pigment, classical giant cell features, and in original tumor, xanthoma cells.

Fig. 2a

Fig. 2. Case 2. a, Recurrent synovial sarcoma of fourth flexor tendon. Skin ulceration produced by intensive irradiation therapy. b, Photomicrograph showing histiocytic evolution of tumor similar to that in Figure 1b. $\times 40$.

In the slide of the recurrence there was considerable modification of the tumor probably as the result of the intensive irradiation. Here the tumor was sparse in loose fibrous stroma and was composed of syncytium of markedly degenerated spindle and irregularly shaped cells with indistinct cytoplasmic borders. In many areas where the nuclei were better preserved they had the same pale oval epithelioid-like aspect encountered in the primary tumor. Elsewhere they were shrunken and irregular. Here the tumor was robbed of its specific synovial characteristics. It could be traced, however, into the substance of the flexor tendon establishing its point of origin. Section through the base of the underlying metacarpal bone shows no evidence of infiltration by tumor.

In December 1939, patient had no evidence of generalization and was free of symptoms of disease. Chest roentgenograms at this time were negative.

Black's tumor was apparently benign although there was only a 10 month period of follow-up which seems inadequate to assure the benignity of the tumor. We regarded this tumor as malignant. Black subsequently reported a synovium of the great toe and added additional follow up information of his first case occurring in the finger indicating that the course after 2½ years was still that of a benign tumor. It may well be that small synoviomias in the tendons of the finger may run a more favorable course than the larger tumors about the larger articulations.

CASE 3: Synovium of left popliteal space, probable origin in semimembranous tendon sheath, treated by two local excisions, well 2 years later.

H. B. male, aged 43 years, was admitted to another hospital, on July 3, 1937, with history of a mass in the left popliteal space and slight stiffness of the knee joint for 6 months.

Examination of the knee revealed a hard, round mass about 2 by 3 inches located just below and in

Fig. 2b

the lower third of the left popliteal space. The mass was fixed to the deep tissues, but not to the skin.

X-ray film of the left knee in the anteroposterior and lateral views showed a circumscribed tumor approximately the size of an egg, in the popliteal fossa. There was no destruction of adjacent bones.

On July 3, 1937, through a transverse incision over the most prominent part of the mass, a firm circumscribed tumor was dissected out of the popliteal space. Sharp dissection was required to free it from the tendon sheaths and from the posterior capsule of the knee joint.

Pathological report August 2, 1937: The tumor, from left popliteal space, was a pinkish-gray ovoid mass 6 by 4 by 3 centimeters in diameter with firm small tags of fat adherent to the surfaces. Five tags and two or three almond-shaped bodies which looked something like lymph nodes were adherent to the surface.

Histological examination showed that the stroma of the specimen consisted, for the most part, of polygonal and spindle cells with large numbers of large multinucleated giant cells. Moderate numbers of tumor cells revealed the presence of hemosiderin pigment in the cytoplasm. Some of the tumor cells were large and contained lipid substance.

Diagnosis: Giant cell sarcoma of tendon sheath (or thomatous epulis).

Patient made an excellent postoperative recovery and was discharged on August 6, 1937. He was readmitted to the hospital on November 1937 with recurrence of the tumor.

Examination revealed a well-healed scar beneath which there was a firm, rounded mass in the medial

Fig 13. Case 13. a, Photograph of drawing of specimen, $\frac{1}{2}$ actual size. Note the clefts and the areas of pigmentation. b, Roentgenogram of original tumor in popliteal space. c, Photomicrograph of a representative area of tu-

mor illustrating synovial border. The evolution of the tumor is histiocytic and essentially similar to that shown in Figures 10b and 11b. Note the multinucleated giant cells and the coarse deposits of hemosiderin to the right. $\times 65$

and posterior aspects of the left popliteal space, about $3\frac{1}{2}$ by $1\frac{1}{2}$ inches

Through a vertical curved incision with the convexity toward the inner side, a tumor was exposed deep in the popliteal space. It was adherent to overlying muscles and tendons, and firmly adherent to the capsule. In removing the tumor it was necessary to remove a portion of the posterior capsule.

Pathological report. The tumor is circumscribed but does not have a distinct capsule. It measures 5 by 5 by 2 centimeters. Some loose tags of fibrous tissue are attached to the surface. On section the tumor cuts with a fibrous consistence and shows one fairly large cystic area about 1 centimeter in diameter. Scattered over the cut surface are firm, yellow, ground concentric nodules which have the consistence of cartilage. The intervening stroma is tinted in various shades from yellow to brown, the pigmentation being similar to that seen in xanthomatous giant cell tumor.

Because of the previous diagnosis of xanthomatous giant cell tumor, this tumor was studied by multiple section through a great many areas. The periphery of the tumor appeared largely encapsulated although the capsule was not complete. On superficial examination, there was found a striking dissemination of multiple deposits of intracellular hemosiderin pigment similar to that seen in xanthoma. Vast areas of the tumor presented a fibrocellular aspect, the cells being rounded, oval, blunt spindle, and irregularly shaped with oval and reniform nuclei. The arrangement of the cells was syncytial and this was better demonstrated by reticulum stains which showed both a fine and a coarse arborescent reticulum supporting the majority of the cells. In many of the areas, the stroma cells could be seen differentiating into multinucleated giant cells containing from 2 to 20 nuclei. In some fields giant cells were particularly numerous. Mitotic figures were fairly numerous about two per high power field. In many areas corresponding to the macroscopic concentric nodules, the stroma could be seen differenti-

ating into fibrocartilage. With both hematoxylin and eosin and Sudan III stains, *it was not possible to demonstrate lipid in the tumor.* Along one edge of the tumor was a well defined synovial border probably that of the semimembranosus tendon. This border showed reduplication of the synovial border cells and multiplication of the subsurface cells with areas of blood pigment similar to hemorrhagic villous synovitis as described in the knee joint.

Throughout the main tumor mass were numerous synovial spaces lined by from one to three rows of polygonal and flattened cells, and these spaces contain a metachromatic mucoid substance.

This tumor represents a form of synovial sarcoma histologically closely related to the xanthomatous giant cell tumor. It has been referred to as the "tendon sheath" type. It differs from xanthomatous giant cell tumor in the presence of typical synovial spaces, the presence of circumscribed areas of fibrocartilage, and the rarity or absence of demonstrable xanthoma cells in the recurrence. No exception is taken, however, to the report of xanthoma cells being present in the original tumor. While the presence of foam cells is a striking feature of xanthomatous tumors histiocytic tumors are frequently found with little or no demonstrable lipid. Berger in his Case 5 has reported what he regards as the first example of a malignant transformation of a xanthoma giant cell tumor in a white man 50 years of age, located in the anterior aspect of left thigh. This is identical with Berger's Case 5 showing synovial borders filled with blood pigment, classical giant cell features, and in original tumor, xanthoma cells.

Fig. 4. Case 4. a, Photograph of drawing of bisected specimen, $\frac{1}{2}$ actual size. Note the cystic center, the nodular cut surface and the dark pigmentation. b, Roentgenogram of original tumor in popliteal space. c, Drawing of specimen, $\frac{1}{2}$ actual size, showing recurrent tumor of suprapatellar pouch and articular synovium. d, Photomicrograph, reticulum stain, confirming histiocytic character of tumor. Hematoxylin and eosin sections identical with that in Figure 3c. X75.

The general feature of the disease, the polymorphous aspect of the cells, is typically histiocytic. Because of the second recurrence with extensive invasion of the thigh muscles Berger's Case 5 was treated by disarticulation of the hip.

Case 13 is identical with Case 14. Both of these tumors showed prompt local recurrence; the recurrence in Case 14 being intra-articular and invasive. Neither the recurrence of Cases 13 nor 14 showed xanthoma cells, although they showed classical histiocytic features otherwise similar to xanthomatous giant cell tumor. It is our belief at the present time that these tumors constitute a less malignant variety of synovial sarcoma more likely to prove

locally malignant. On the other hand the tumor showed many features of Case 10 which proved malignant and capable of metastasis. The course of these 2 cases together with Berger's Case 5 will undoubtedly further establish the degree of malignancy of this type.

CASE 4. Synovium of right popliteal space recurring after 4 months within the knee joint. Treated by local excision, synovectomy and amputation.

C. G., male, aged 46 years, was first seen in the clinic of the Hospital for Ruptured and Crippled on December 6, 1931, complaining of swelling and pain in the right knee beginning 1 month previously without any apparent cause. He had visited physician concerning it, had been given some oral

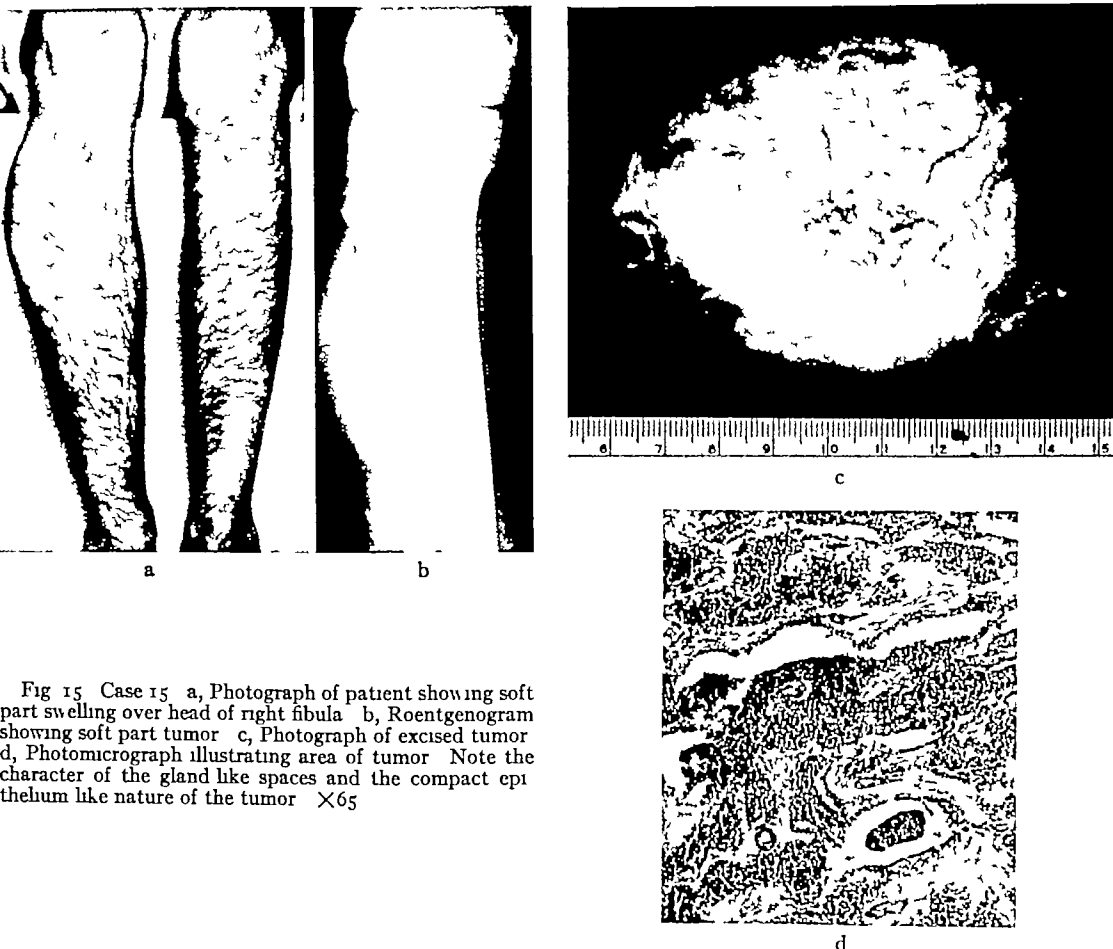

Fig 15 Case 15 a, Photograph of patient showing soft part swelling over head of right fibula b, Roentgenogram showing soft part tumor c, Photograph of excised tumor d, Photomicrograph illustrating area of tumor Note the character of the gland like spaces and the compact epithelium like nature of the tumor $\times 65$

medication, and swelling subsided after 2 weeks. His past history was negative regarding any important illnesses.

Examination revealed a slight fullness of the entire knee joint, slight ballottement of the patella, and a palpable mass about the size of a walnut in the middle of the popliteal space. This was tense and slightly fluctuant.

Roentgenograms showed fluid within the joint capsule and a well defined density in the popliteal region.

A diagnosis of cyst of popliteal space was made and excision was advised. Patient refused to have this done.

Patient was next seen May 26, 1938, and stated that he had been free from pain until 1 week previous to this visit at which time he had a sudden recurrence of pain and swelling of the right knee. This gradually increased until he was entirely disabled. He had a temperature of 99.2 degrees, diffuse swelling, and generalized tenderness about the knee and some local increase in heat. The previously

noted mass was present in the popliteal space. An aspiration of the knee joint was done and 250 cubic centimeters of a turbid yellowish fluid was obtained. Sedimentation rate was 45 millimeters in 1 hour. The patient was again advised to enter the hospital for excision of the cyst.

On June 1, 1938, the patient consented to operation, and on June 3, 1938, a large firm tumor lying medial to the medial head of the gastrocnemius and originating probably in a semimembranous bursa or tendon was excised.

The specimen was an encapsulated tumor 6 by 4 by 2 centimeters. There was some fat adherent to the capsule. On sagittal section the color was a mottled white and orange and in the center was an area of cystic softening, 1 centimeter in diameter, which contained some jelly like material.

The microscopic features were identical with those in Case 13.

Patient was seen at monthly intervals and occasionally complained of vague aches about the knee. Nine months after operation a mass was noted over

the anterolateral aspect of the right knee in the suprapatella pouch. There was no evidence of recurrence in the popliteal space.

He was readmitted on May 4, 1930.

Examination at this time revealed a healed scar in the popliteal region. Just above and lateral to the patella, there was a mass 4 centimeters in diameter which was firm, freely movable and in the suprapatellar pouch, not tender. There was demonstrable free fluid in the joint.

A diagnosis of recurrent synovoma was made and the patient was operated upon on May 3, 1930, through a large anterior incision. The suprapatellar pouch was found to be filled with a firm pedunculated tumor mass extending back between the condyles of the femur. A total synovectomy was performed and followed by amputation a week later.

The specimen consisted of the resected synovial membrane of the knee joint with some adherent fatty tissue. When laid out, it measured 6 by 10 inches and averaged about $\frac{3}{4}$ of an inch in thickness. Grossly it contained three chocolate brown firm, nodular pedunculated tags of adherent tumor tissue. These had a firm almost cartilaginous consistency. In addition, there was one large red, bumpy, irregular nodular which was also chocolate brown in color and corresponded to the mass which occupied the suprapatellar pouch. The gross appearance of the specimen was not unlike that of diffuse xanthomatosis of the knee joint.

Several microscopic sections of the small fragments were prepared. In general, the recurrence was basically the same as the original tumor.

Patient is alive without evidence of disease May 1930, year after operation.

CASE 15. Synovoma probably originating in bursa or tendon sheath of right biceps femoris treated by local excision followed by deep x-ray therapy. Death within 8 months of extensive pulmonary metastases.

E. B., an American male, aged 4 years, was first seen in the New Haven Hospital in April, 1934, when meningioma of the right precentral region was removed. He recovered completely from this operation and in April, 1936 returned to the hospital. Almost since the brain operation, 2 years before the patient had noticed that his right leg was slightly larger than the left. He had noticed in the last 6 weeks that the right leg had definitely increased in size. There was no history of trauma.

On physical examination there was found over the lateral surface of the proximal half of the right lower leg a firm slightly tender nonreddened oval mass, about the size of a orange. The laboratory findings are negative. A diagnosis of sarcoma of the right leg was made; the patient was operated upon, and the mass excised. The peroneal nerve was found to course through the mass. The patient made an uneventful recovery, left the hospital approximately 1 month after operation. Following the operation he was given a course of deep x-ray therapy through three ports, medial, lateral, and posterior

through the region of the tumor and also to the right inguinal region. A chest plate at the time of the removal of the tumor failed to reveal any evidence of metastatic tumor. The patient re-entered the hospital in August, 1937, because of complaint of cough and chest pain of about 2 weeks' duration. X-ray films revealed the presence of tumor metastases in the mediastinum and accumulation of fluid in both pleural cavities. The pleural fluid contained tumor cells. He expired 11th extensive metastatic tumor on October 4, 1937.

The specimen was an oval mass of three high measures by 7 by 3.5 centimeters. Its external surface was roughened and showed few short tags of muscle and fibrous tissue adherent. The tumor was moderately soft, cut readily and revealed pink-gray cut surface the tissue was succulent and friable and in the central portion had a yellow opaque appearance where it had become necrotic. There was a suggestion of thin fibrous tissue capsule about the tumor which appeared to be invaded by tumor in several places.

Microscopic sections from various portions all showed an essentially similar appearance. The tumor was cellular and was composed of cells of fairly uniform size and shape. They were somewhat polyhedral in outline with finely granular pink staining cytoplasm with round or oval basophilic hyperchromatic nuclei. There were one or two mitoses per high power field. In some fields the cells surrounded connective tissue stalks which gave the tumor a papillary architecture. In other places long slit like spaces lined by flattened tumor cells were seen. These were surrounded by masses of the polyhedral cells. A thin fibrous tissue capsule which was invaded by tumor was present. The tumor also invaded the surrounding skeletal muscle and was also present as tumor thrombi in some of the surrounding blood vessels.

The dominant histological feature was the reproduction of neoplastic villi similar to that in areas of Case 1. Other areas suggested reticulum cell sarcoma.

The following case is of interest because it represents one of the few if not the only autopsy record of a synovial sarcoma.

CASE 16. Synovoma of right tibial tubercle and overlying right lateral epicondyle treated by local excision followed by deep x-ray therapy. Death within 7 months of generalized metastases. Autopsy. S. M., an Italian male aged 45 years, was admitted to the New Britain Hospital on May 6, 1938.

On first admission December 6, 1937, he had complained of swelling on the right lateral aspect of the right arm just above the lateral condyle extending medially to the antecubital fossa. He stated that about 4 days previous to this admission he felt a small nodule about the size of the tip of the

Fig 16 Case 16 a, Nodular pulmonary metastases seen at autopsy b, Photomicrograph of pulmonary metastases,

reticulosarcomatous character $\times 100$ c, Metastases in right ventricular endocardium, about $\frac{2}{3}$ actual size

thumb. The nodule grew in size, without associated pain, heat, or redness, and without impairment of motion.

On the right lateral aspect of the right arm about 1 inch above the lateral epicondyle and extending medially toward the antecubital fossa, was a nodular mass about the size of an English walnut. It was not very hard and appeared to be fixed to the deep tissue, but not to the skin.

Biopsy was performed on December 6, 1937. The pathological diagnosis was malignant synovium, and the patient was discharged on December 10, 1937. Deep x-ray therapy was begun on December 27, 1937.

Examination of microscopic sections revealed a highly cellular tumor composed of a syncytial arrangement of pale endothelium like cells with large oval reniform or rounded nuclei. The arrangement of the tumor was largely perithelial. In areas, however, compact epithelium like cell masses were present.

His second admission was on March 13, 1938, at which time he complained of pain in the back, especially on walking, for the previous 2 or 3 weeks. The

pain was also present posteriorly at both iliac crests. At this time there was some tenderness to pressure over the posterior half of both iliac crests. There was marked point tenderness over the spine at the level of the eleventh and twelfth dorsal vertebrae.

On March 14, x-ray examination of the spine and chest showed two definitely rounded areas in the right lung field, one about the size of a quarter, the other about the size of a silver dollar, both lying in the lower lung field. The left lung showed one soft rounded shadow in the lower portion. There was also destruction of the spinous process of the twelfth thoracic vertebra. Following discharge the patient was admitted to the Memorial Hospital, where further irradiation was given.

His third admission was on May 10, 1938. He complained of excruciating pain in the right lower chest and some pain in the left chest, right sacrum, and lower posterior back. There was also pain in both legs. At this time there was some tenderness of the right upper abdomen and the liver appeared to be enlarged. Palpation of the lower back revealed marked tenderness over the right sacrum and isch-

tum. There was an area of tanning of the lower back where the patient had received x-ray therapy. His temperature fluctuated between 90 and 100 degrees. During the last week, it was constantly elevated and ranged between 100 and 105 degrees. On this admission there was a bald area on the right side of the scalp where there had previously been a tumor. There was also tenderness about the size of a large walnut over the left parietal region. Deep x-ray therapy was continued but the patient's condition became worse. On May 23d, while going to the bathroom he placed his arm on the door and sustained a pathological fracture.

He continually complained bitterly of pain in the right sacrum and right leg. Antineoplastic serum was administered in three doses with marked relief of the pain. He continued to fall however and on June 3 became comatose. He expired on June 14, 1938.

Clinical diagnosis. Malignant synoviomia of the right elbow with multiple metastases to lung and bones.

Autopsy examination was permitted. Subject was an emaciated, dolt, white male, weighing 100 pounds, body length, 164 centimeters.

Two soft rounded fluctuant tumor nodules were located in the right and left parietal regions. In the right upper extremity about 3 centimeters above the lateral condyle there was a firm, rounded mass not attached to the skin. Medially and anteriorly above the antecubital space was a smaller, similar nodule about centimeter in diameter. The large nodule was located near the upper end of the healed linear scar which represented the site of the previous operative incision. There was a fracture of the upper third of the left humerus.

When the abdominal cavity was opened, a small, firm hemorrhagic red nodule 3/4 centimeters in diameter was found in the greater omentum, and several similar but smaller nodules were found on the lesser omentum near the attachment to the stomach.

One nodule was found in the right ventricle and one in the left ventricle of the heart.

Both lungs were large, heavy and studded with innumerable nodular metastases.

The pancreas showed an area of tumor tissue invading the tail of the organ.

There were no metastases to the liver, adrenals, spleen, kidneys, or gastro-intestinal tract.

Nodular metastases occupied the fifth, sixth, seventh, and twelfth ribs.

Summary of the findings, therefore, indicates local recurrence of the tumor with widespread metastases to the lungs, heart, pancreas, ribs, dorsal vertebra, omentum, scalp, and left humerus.

In the metastases of the tumor as seen in the lung, the tumor was composed of small, rounded nuclear elements about the size of lymphocyte supported by a fine delicate reticulum. Here the aspect was typical of certain forms of reticulosarcoma.

SUMMARY

A study of the 16 personally observed cases of synovial sarcoma comprises the largest single series to be reported in the literature and enables one to draw certain conclusions of the clinical course and histological behavior of this condition.

Histologically all the varieties of synovial sarcoma, however extreme and variable they may appear to be, exhibit specific characteristics which permit of their identification. Nor is the time far distant when the malignancy and radiosensitivity of this tumor will be graded as accurately as is now possible for other malignant tumors.

The evolution of all synovial sarcomas may be correlated with various functional and histological characteristics of normal synovial tissue. The characteristics previously mentioned are here reiterated.

1. An endothelial structure and function. The lining synovial cell represents a differentiated form of synovial histiocyte destined to play a border or endothelial function. In the synovial sarcoma, the endothelial function is frequently exhibited as glandlike spaces resembling adenocarcinoma, as sheets or nests of epithelium-like cells, as neoplastic villi or as well differentiated synovial borders. In order of malignancy these tumors appear to lie midway between the classical histiocytic tumors and the reticulosarcomas (Grades 2-3).

2. A histiocytic structure and function. Normal synovial tissue develops as a histiocytic tissue in the embryo where numerous argyrophilic threads are present. In adult life this histiocytic property persists, and is exemplified by lipophagic, siderophagic, and anthrophagic potentialities. The histiocyte is a relatively totipotent mesenchymal element and is capable of wide ranges of differentiation and dedifferentiation. Microscopically the histiocytic tumors exhibit themselves in several forms. A classical polymorphous histiocytic aspect with giant cells, intracellular inclusions of blood pigment as tumors with classical giant cell features, not greatly different from xanthomatous giant cell tumor. Islands of xanthoma cells may be occasionally present. The behavior of this variety of syn

ovial sarcoma suggests malignancy of a low order (Grades 1-2)

3 Synovial sarcoma may appear as a de-differentiated fibroblastic tumor generally indistinguishable from fibrosarcoma or spindle cell sarcoma unless synovial clefts or small areas of reticulo-endothelial evolution are located. Identification requires multiple sections and careful differential staining. The malignancy of this type would appear to follow closely that of fibrosarcoma and spindle cell sarcoma. In general, slow growth and late metastases is the rule. Moreover, calcification, chondrification, and ossification probably succeed a type of albuminoid impregnation of the tumor and when present in a tumor whose location suggests a synovial origin, should lead to further attempts to establish the specificity of the tumor.

4 Mucin formation is not infrequently exhibited in synovial sarcomas and appears to be confined to the endothelial cell components.

5 Clinically, synovial sarcomas in knee joints extend over a long insidious pre-operative course covering an average period of 5-6 years. The surgeon therefore has a reasonably long period in which to institute radical therapeutic procedures and must be ever on the alert for atypical forms of so called synovitis.

6 Synovial sarcomas in other para-articular regions manifest themselves more readily as soft part tumors usually after an average period of a few to several months. The poor end-results are undoubtedly caused in part by the procrastination of the patient and of the surgeon.

7 Amputation is the treatment of choice for all synovial sarcomas. It may be justifiable in instances when the tumor is small and encapsulated, to perform wide local excision and defer amputation until pathological examination has permitted time for histological study. Amputation should never be deferred beyond the time of the first recurrence.

The authors wish to acknowledge their indebtedness to the following physicians without whose help it would not have been possible to accumulate these cases: Bradley L. Coley, Walter Philips, Guilford Dudley, Winthrop Phelps, George Van Gorder, Merrill A. Lindsay, Lewis Clark Wagner, Richmond Stephens, Douglas Symmers, Tracy B. Mallory, Dennis O'Connor, Norman Treves.

BACTERIAL FLORA OF ACUTE TRAUMATIC WOUNDS

E. J. PULASKI M.D. and F. L. MELENEY M.D. F.A.C.S. New York, New York

WILLIAM L. C. SPAETH M.D. Philadelphia, Pennsylvania

TRAUMATIC wounds present conditions in regard to the possibility of infection which are quite different from those ordinarily encountered in aseptic surgery. Bacteria, both aerobic and anaerobic, are carried into the tissues from the surrounding skin as well as on clothing and other foreign bodies introduced by the agents producing the trauma. Tissues are destroyed to a variable degree and such devitalized tissues furnish an excellent medium for bacterial growth. Certain of the contaminating bacteria may produce a violent spreading infection including the dreaded gas gangrene. Bacterial cultures, therefore, become a necessary basis for the intelligent treatment of accidental wounds. This study concerns itself with the analysis of the bacterial flora cultivated from 200 acute traumatic previously untreated wounds.

The older studies on the bacteriology of accidental wounds were in many instances inadequate because of lack of satisfactory anaerobic and aerobic methods of cultivation. The means of obtaining the cultures were not always such as to bring to light every type of organism present. Often cultures were secured from only one part of the wound and without the benefit of anaerobic bacteriological studies.

Riggenbach (1898) was probably the first to suggest the importance of anaerobes as well as aerobes in accidental wounds. His method was to swab the surface of the wound with cotton which was inoculated into broth, one-half being incubated aerobically and one-half anaerobically. From 24 cases he isolated *Staphylococcus albus*, 14 times; *Staphylococcus aureus*, 4 times; streptococci (kind not mentioned) 6 times; *Micrococcus tetragenus*, 5 times; pneumococci, twice; Friedländer's bacillus and *Bacillus coli* once each. *Clostrid-*

ium tetani was seen twice. No mention is made of other anaerobes. He found that all the wounds showed a mixed flora, either with saprophytes which were easily identified or sometimes, with unknown rods and cocci. He concluded that wounds may contain pathogenic bacteria without clinical evidence of infection, these disappearing as healing progresses.

There is an enormous literature on the bacterial flora of war wounds of the First World War (3). These studies are important in that they directed attention to the frequency with which gas gangrene producing anaerobes could be cultivated from wounds, especially the deep puncture wounds and muscle traumatism in which soil, clothing shrapnel, etc. were implanted in the depths of the wound. The bacterial flora present varied according to the type of injury, the technique for cultivating the organisms, the manner in which the cultural material was obtained, the time interval from injury to the making of the culture, et cetera. Another important contribution from these studies was the observation that a combination of gas gangrene organisms with hemolytic streptococci produced a more virulent gangrenous infection than the anaerobes alone. Zetsler (1928) reported 21 cases of traumatic injuries in which anaerobes were isolated in each case. In 3 anaerobes were present without clinical evidence of anaerobic infection in 8 cases there were anaerobes found with clinical evidence of infection and recovery. In the 10 remaining cases the anaerobic infections were fatal. Anaerobes alone were isolated from 13 of the wounds. Aerobes and anaerobes were combined in the 8 others. The anaerobes grown were *Clostridium welchii*, 21 cases; *Clostridium oedematiens*, 7 cases; *Vibrio septique*, 1 case; *Clostridium histolyticum*, 1 case; *Clostridium tetani*, 3 cases. Of the nonpathogens there were *Clostridium tertium* 4 cases; *Clostridium sporogenes*, 3

From the Clinical Laboratories, Franklin Hospital, Philadelphia, Pennsylvania, and the Laboratory for Bacteriological Research of the Department of Surgery, College of Physicians and Surgeons, Columbia University, New York.

cases, and *Clostridium bifermentans*, 1 case

Sas (1930) studied 55 accidental wounds, a few minutes to 20 hours after injury—in most cases one-half hour's duration—by introducing two sterile silk knots into the wound "until they were saturated with the wound secretions," then culturing the knots aerobically and anaerobically. The pyrogallic acid-alkali method for culturing anaerobes was used. He isolated *Staphylococcus albus*, 23 times, 41.8 per cent, streptococci (kind not mentioned), 19 times, 34.5 per cent, *Staphylococcus aureus*, 11 times, 20 per cent, *Bacillus coli* group, 5 times, 9 per cent, *Staphylococcus citreus*, twice, 3.6 per cent, pneumococci, twice, 3.6 per cent, gas producing anaerobes, 11 times, 20 per cent. Eight of the anaerobes were identified as *Clostridium welchii*. Not all of the bacteria could be identified. Among the saprophytes were found 16 bacilli, 23 cocci, 7 sarcinae, 1 streptothrix. He concluded that accidental wounds are always contaminated and are more serious than clean operative wounds, especially because gas gangrene producing bacilli may be present without any manifest infection.

Veraart and Dreuth (1930) cultured swabs from secretions of 215 fresh, previously untreated wounds with the following results: 41 per cent of the cases were sterile, 15.5 per cent yielded 100 or more colonies of bacteria. After intensive cleaning with hydrogen peroxide, dilute spirits and ether, then 5 per cent tincture of iodine, 86.5 per cent were sterile and in the remainder there were no wounds which showed more than 100 colonies.

Dimitza and Gutscher (1933) studied 424 wounds by culturing all the excised tissue débrided. Ninety-two cases were found bacteria-free. The 332 others showed staphylococci alone in 108 cases, and mixed with streptococci and colon bacilli in 59 cases, streptococci alone in 31 cases, and mixed with staphylococci and colon bacilli in 62, colon bacilli alone in 10 cases, and mixed with staphylococci and streptococci in 21, *Clostridium welchii* in 57 cases. They believe that the high incidence of *Clostridium welchii*, 20 per cent, indicates that gas gangrene must always be reckoned with, especially in railroad and street accidents, all cases of which showed contamination with

these organisms. However, gas gangrene did not develop in all these cases, clinical symptoms having occurred in only 8. The *Clostridium tetani* was isolated twice, both times from street accident cases, but tetanus did not develop in either.

Sviridov (1936) studied both bacteriologically and clinically 120 acute traumatic wounds before and after *épluchage* and *débridement*, by direct smear of the wound surface at the level of the skin, the muscle and bone, and by cultures from the same levels. Anaerobic cultures were not made because of lack of equipment. There were 45 skin wounds, 38 skin and muscle, and 37 skin, muscle, and bone injuries. One hundred cases were treated by *épluchage* and 20 by *débridement*. In 100 cases before *épluchage* he found streptococci (kind not noted) in 13 cases, staphylococci in 25 cases, diplococci in 5 cases, staphylococci with streptococci in 8 cases, streptococci with diplococci in 6 cases, streptococci, diplococci, and staphylococci in 1 case, *Bacillus coli* in 7 cases, *Bacillus subtilis* in 14 cases, other cocci in 21 cases, yeast cells in 2 cases, other saprophytes in 71 cases. After *épluchage* 27 cases showed pathogenic flora, 28 saprophytes only, and in 45 cases no growth was obtained. Eighty-three of the cases healed by primary intention and 17 suppurred. In the latter staphylococci were grown 5 times, streptococci, 3 times, streptococci with staphylococci, 2 times, and *Bacillus coli* in 1 case. After *épluchage* 15 per cent of the cases which healed by primary intention gave growth on culture, yet infection did not take place. All these were face and skull wounds. Wounds in this area possess greater resistance to infection and heal by primary intention in 86 per cent of the cases. Wounds of the thigh, shoulder, and pelvis with muscle and bony involvement give the most unsatisfactory results, due to the frequent inability to remove completely all the contaminated tissue. In 20 débrided wounds 1 case of gas gangrene and 1 case of osteomyelitis developed. Both recovered.

Levaditi (1939), during the present World War, cultured wound secretions on cotton swabs from 68 wounds, including 35 flesh wounds, 22 compound fractures, 7 accidental wounds, and 4 amputations, 75 per cent of

<i>Diphtheroids</i>			6		6		12										12	(1)
<i>Gram-negative cocci</i>			1										20	20			1	(1)

the cases contained 3 bacterial species or less 1 case was sterile, and the others contained 4, 5 or 6 species. The types of organisms isolated were staphylococci 85 per cent streptococci (kind not stated) 58 per cent *Escherichia coli*, 41 per cent enterococci 28 per cent *Clostridium welchii*, 17 per cent *Bacillus pyocyaneus*, 7 per cent. Other types commonly isolated were sarcinae *Bacillus subtilis* and *Bacillus proteus*.

Rathcke (1940) studied excised tissue fragments from 140 wounds. (*Clostridium tetani*) pathogenic for mice, were isolated from 6 wounds—1 street accident, 2 agricultural 1 sport 1 railroad and 1 glass injury. Other organisms found were various clostridia (kind not mentioned) 22 times staphylococci, 109 times streptococci (kind not mentioned) 28 times *Bacillus coli*, 7 times aerobic spore bearing rods, 29 times gram positive non spore bearing rods 16 times diphtheroids, 16 times enterococci, 8 times actinomyces, once other bacteria, 5 times. Two wounds yielded

no growth. He recommends prophylactic anti tetanus serum for all accidental injuries.

The results obtained by the different authors presented are difficult to compare because of the lack of uniformity of method of selecting material for examination. The studies of Vernaart and Dreuth, and Dimiza and Gut scher are surprising as regards the large number of cases from which sterile cultures were obtained. It might have enhanced the value of these investigations had the distinction been made between clinically clean and dirty wounds likewise any relationship between the types of contaminating organisms and the age of the wound. In this study we have attempted to evaluate some of these factors.

MATERIAL AND TECHNIQUE

Fresh, accidental wounds, both in ambulatory and hospitalized cases, were studied. Cases of patients who had any form of treatment prior to arrival in the hospital were not included. The material for study was collected

in the Accident Room and Surgery of the Frankford Hospital, Philadelphia, Pennsylvania, and the Emergency Ward of the Presbyterian Hospital, New York. The types of wounds included deep and trivial lacerated wounds, bullet, dog and human bite and other puncture wounds, machine and automobile accidents, traumatic amputations, and compound fractures. Most of the cases were lacerated wounds. Many were street accidents. The time period from injury to culture varied from a few minutes to 24 hours. The majority of cases comprised patients seen within one-half hour of the time of injury. It was difficult to obtain study material on cases longer than 1 hour's duration. Most of such patients had some form of antiseptic treatment applied en route to the hospital.

In collecting material we wished to cultivate not only the contaminating organisms deposited on the surface of the wound but also those lodged in the crevices and interstices. It was decided therefore to excise the traumatized tissue to the extent that it was representative of the wound as a whole, and to culture the excised tissue *in toto*. All our cultures, therefore, represent the bacterial flora present in tissue fragments débrided under general or local anesthesia, and prior to the institution of any treatment. As soon as the tissue was débrided it was introduced into tubes or flasks of liquid

culture media. Rosenau's brain dextrose medium was first used. Later thioglycollate (1) media was substituted, its use obviating the necessity of preheating the media to drive off the contained air. We found the thioglycollate medium satisfactory for our purposes. The inoculated media was then taken to the laboratory accompanied by a slip stating the site, extent, and duration of the injury, with notation as to whether the wound appeared clean or dirty. We consider swab cultures inadequate.

The cultures were incubated overnight. If any failed to show turbidity, further incubation was done. The contents were mixed by means of a Pasteur pipette and a portion of the culture was removed and streaked on a pair of 5 per cent sheep's blood agar Petri plates. Another drop was placed on a glass slide for Gram stain. One plate was incubated aerobically and the other anaerobically in a McIntosh-Fildes type jar, evacuated to 350 millimeters mercury by means of a water pump, then slowly filled with hydrogen streaming over heat-activated palladiumized asbestos until a positive pressure was obtained. The aerobic plates were examined the next day, the anaerobic plates usually after 48 hours' duration. If there was no growth, the incubation of negative cultures was continued for 48 hours. When growth appeared on the plates, all the various colony types were fished and identi-

fied in the usual way by morphological and cultural studies. Most cultures were replated before discarding for check on the original findings. Virulence tests on pathogens groupings of the hemolytic streptococci, and coagulase tests on the staphylococci were not made. Molds and fungi were not identified.

RESULTS

Two hundred cases were studied, comprising 102 clinically clean cases, and 98 "dirty" or foreign body contaminated cases. The findings in the number of cases procured in each time period are presented in Tables I and II. The distribution of cases according to aerobic and anaerobic organisms cultivated is presented in Table III.

TABLE III.—AEROBIC AND ANAEROBIC ORGANISMS ISOLATED

	Clean		Dirty		Total	
	Cases	Per cent	Cases	Per cent	Cases	Per cent
Aerobes alone	66	74	52	54	118	66.5
Anaerobes alone					6	6
Aerobes plus anaerobes		6	42	43.8	48	24
	102		98		200	

The clinically "clean" cases predominate in the 5 and 10 minute groups, while in the older wounds there were more of the "dirty" cases. Six hundred and six different bacterial species were cultivated, making an average of 3 per wound. Aerobes alone were present in 133 cases or 66.5 per cent of the total. Anaerobes alone were cultivated from only 3 cases, 1.5 per cent dirty wounds. Aerobes plus anaerobes were grown from 64 wound débridements, 32 per cent of total. All of the wounds studied yielded positive cultures. This is in contrast to the reports of Dumize and Gutacher who found 92 wounds sterile 21.7 per cent, in a total of 424; the technique for study being similar to this one and to those of Verhart and Dreuth who reported 41 per cent of the cultures of 215 cases, sterile by the cotton swab method.

Anaerobes were present in 22 of the "clean" cases, 21.6 per cent of total, as against 42 of the dirty cases, 43.5 per cent of total. The

presence of foreign bodies in dirty wounds, especially street dirt undoubtedly contributes to the preponderance of anaerobes.

The percentage of anaerobes increased with the older wounds. Mason believes that organisms from human sources contaminating wounds usually gain entrance after rather than at the time of injury and that they may be introduced by the application of a soiled dressing or by handling the wound without proper aseptic precautions. It may be conjectured that these factors explain the increase in anaerobes noted in the older wounds.

Staphylococci From the foregoing tables it is evident that these organisms can be isolated from nearly every wound. As is well known, however staphylococci can be cultivated at will from the unbroken skin. The *Staphylococcus albus* was isolated 162 times, 81 per cent of cases, and the *Staphylococcus aureus* from 104 wounds, 52 per cent of cases. The distribution of both *Staphylococcus aureus* and *Staphylococcus albus* was about equal between the clean and dirty cases. Pigmentation is by itself of limited value in the differentiation of staphylococci. Division on the basis of hemolysis and production of human plasma coagulase has recently been shown to be advantageous, and in future studies this classification will be adopted. *Staphylococci* were found alone in only 7 instances. Associated with *Staphylococcus aureus* in 99 cases were *Staphylococcus albus*, 78 times; streptococci, 55 times (hemolytic, 17; green, 11; nonhemolytic, 27); gram positive aerobic spore bearing bacilli 33 times; clostridia, 23 times; enterobacteria, 11 times; micrococci and sarcinae 29 times. Anaerobic organisms were isolated in conjunction with *Staphylococcus aureus* 33 times.

Streptococci Next in frequency to the staphylococci, streptococci were recovered from 101 wounds, 50 per cent, 105 isolations were made. The nonhemolytic variety accounted for 53 of this number 40 being aerobic and 13 anaerobic. The hemolytic streptococcus was grown from 34 cases—aerobic, 25; microaerophilic, 9. Green streptococci were cultivated 18 times. The distribution is of interest. The clinically clean wounds showed the nonhemolytic streptococcus in 35 cases, 33.3 per cent (aerobic, 29; anaerobic, 6) and

the hemolytic species in 9 cases, 9 per cent. However, in the dirty cases, the hemolytic streptococcus was isolated 25 times—aerobic, 18, microaerophilic, 7, 25 4 per cent—while the nonhemolytic variety was found 18 times, 18 2 per cent. The green streptococci were found in the same proportion in clean and dirty cases. Pure cultures were rarely found. The organisms commonly isolated with the streptococcus are given in Table IV. It would have been of considerable interest to have grouped the hemolytic streptococci according to Lancefield's classification.

TABLE IV — ORGANISMS COMMONLY ISOLATED WITH THE STREPTOCOCCUS

	Staphylococcus albus	Staphylococcus aureus	Hemolytic streptococcus R	Hemolytic streptococcus N	Nonhemolytic streptococcus R	Nonhemolytic streptococcus N	Green streptococcus	Clostridia	Enterobacteria	Bacillus subtilis group	Total cases
Nonhemolytic streptococcus R	32	20	1	0	—	0	1	7	7	8	40
Nonhemolytic streptococcus N	12	5	1	0	0	—	1	2	2	5	13
Hemolytic streptococcus R	19	14	—	0	1	1	1	12	2	13	25
Hemolytic streptococcus N	8	4	0	—	0	0	0	1	2	3	9
Green streptococcus	11	12	1	0	1	1	—	2	2	6	18

R—aerobic
N—anaerobic

Clostridia. This important group of organisms was isolated from 46 cases, 23 per cent of total. They contaminated the dirty wounds 3 times as frequently as the "clean" ones—34 6 per cent as against 11 1 per cent. Interestingly, the older the wound the more frequently were clostridia isolated from it. The same held true for the "clean" as well as the dirty wounds. The varieties isolated included *Clostridium welchii*, 24 times, *oedematiens* (novyi), twice, *bifermentans*, once, *multifermentans*, 3 times, *histolyticum*, twice, *aerofetidum*, once, *tetani*, 3 times, *tertium*, 3 times, *sporogenes*, twice, *botulinum*, once, *chauvei*, once, not identified, 3. The organisms isolated with the clostridia were *Staphy-*

lococcus albus, 39 times, *Staphylococcus aureus*, 22 times, streptococci, 24 times, gram positive aerobic spore-bearing bacilli, 17 times, enterobacteria, 8 times. No cases of gas gangrene and no cases of tetanus infection developed in the wounds from which these organisms were grown, treatment being instituted to prevent their activity. While the presence of these organisms in a wound does not guarantee infection, their high incidence is a forceful argument for keeping this possibility constantly in mind and for taking any possible steps to avoid it.

Enterobacilli. Forty-nine, or 24 5 per cent, of the wounds studied showed gram negative bacilli on cultivation, their presence being about equal in both the clean-looking and the dirty wounds. They were cultivated most commonly from hand and leg wounds, and least frequently from scalp wounds. The varieties isolated included *Escherichia*, 13, *Proteus*, 13, *Eberthella*, 11, *Shigella*, 3, *Alkaligenes*, 2. Other gram negative bacteria isolated were *Bacillus pyocyaneus*, 2, *Friedlaender's bacillus*, 1, *Bacillus prodigiosus*, 1.

The *Proteus* group was predominantly in the dirty wounds, 10 of the 13 isolations being in this group. The *Eberthella* group was predominant in the "clean" group, 7 of the 11 cases.

The organisms isolated in association with the gram negative bacilli were *Staphylococcus albus*, 40 times, *Staphylococcus aureus*, 11 times, hemolytic streptococci, 4 times, nonhemolytic streptococci, 10 times, *Bacillus subtilis* group, 24 times, clostridia, 10 times, micrococci, 7 times, diphtheroids, 4 times.

Anaerobic gram negative bacteria are rare, 3 cultures only having been obtained. They were *Bacterioides fragilis* from a finger wound, *Colibacterium molniformis* from a wrist wound, and *Bacterioides tenuis* from a scalp wound. *Staphylococcus aureus* infection developed in the wrist wound.

The saprophytic organisms isolated include the gram positive aerobic spore-bearing bacilli, 77 times, 41 6 per cent of the cases, the micrococci, 46 times, 25 per cent of the cases, and the gram negative cocci, 3 times, 1 6 per cent. Molds were relatively infrequent, found in 9 wounds, 4 5 per cent of the cases.

SUMMARY

Accidental wounds are always found to be contaminated no matter how early they are seen after injury. In 200 fresh, previously untreated traumatic wounds cultures of débrided tissue showed bacteria present in every case. The types of wounds included lacerations, bullet dog and human bite, and other puncture wounds machine and automobile accidents traumatic amputations and compound fractures. Contamination occurs usually with pathogenic and often with virulent organisms. Dirty wounds are apt to show hemolytic streptococci and the gas gangrene producing anaerobic bacilli more frequently than clean wounds. However even clean-looking wounds may harbor these organisms with sufficient frequency to suspect their presence in every case. No one can tell which of these wounds is going to develop infection.

The important bacteriological findings in 200 cases are as follows: *Staphylococcus aureus*, 104 times, 52 per cent hemolytic streptococcus 34 times 17 per cent nonhemolytic streptococcus, 53 times 26.5 per cent green streptococcus, 18 times, 9 per cent clostridia, 46 times, 23 per cent enterobacteria, 46 times, 23 per cent and the anaerobic gram negative bacilli 3 times, 1.5 per cent. These organisms were rarely found in pure culture. (In many instances 2 or more pathogens were cultivated from the same wound.) Saprophytes, the gram positive aerobic spore bearing bacilli and gram positive cocci, were frequently seen. An average of 3 different organisms was isolated from each wound. The older the untreated wound the more commonly were anaerobes cultivated.

The knowledge of the bacterial flora in any given contaminated wound gives a sound basis for the rational prophylactic treatment to be instituted to prevent infection in that wound.

NOTE: The characteristics of the staphylococci in 33 of the 200 cases are studied. Fifty-one different colonies are

isolated in pure culture. Of these 30 are orange pigmented (aureus) and one blue (albus) variety. Thirty colonies are hemolytic on sheep's blood agar plates. All are pigmented (aureus). Nine of the pigmented strains are nonhemolytic.

Fresh undiluted oxalated human plasma and 4 hour dextrose broth cultures are employed in testing for coagulase. The development of firm coagulases after 6 hours incubation at 37 degrees C. as indicated by the presence of coagulase. Fourteen strains (8 cases) are coagulase positive. All these are hemolytic and pigmented. Sixteen hemolytic pigmented strains are coagulase negative and nonhemolytic strains are also coagulase negative. The latter include the nonpigmented albus strains.

The authors gratefully acknowledge the help and co-operation of D. C. J. Gieseler, of the Franklin Hospital, Philadelphia, in securing material for study.

SULFATHIAZOLE AND SODIUM SULFATHIAZOLE IN THE TREATMENT OF POSTOPERATIVE PNEUMONIA

WESLEY W SPINK, M D and CARROLL J BELLIS, M D ,
Minneapolis, Minnesota

IT is generally recognized that postoperative pulmonary complications are frequently encountered. The purpose of this communication is to present the results of therapy with sulfathiazole in a group of patients having postoperative pneumonia. Since "postoperative pneumonia" is a term that is often used quite loosely, it is first necessary to clarify its meaning. One of the most significant contributions made to this subject was that of Whipple in 1918. Using the term, "postoperative pneumonitis," he called attention to a little recognized but common form of postoperative pulmonary complication. This type occurred in the first 24 to 48 hours after operation, and its features were a rise in temperature, cough, increased respiratory rate, chest pain, and dullness over a portion of the lower lobes. Within a few days the symptoms subsided, the temperature declined by lysis, but the physical signs of consolidation persisted for a longer period of time. Pneumococci of the higher types were frequently isolated from the sputum of these patients. The mortality rate was low. In the light of subsequent studies by others, it is probable that the patients observed by Whipple had some degree of atelectasis associated with a low-grade pulmonary infection.

The careful clinical observations of King recorded more recently have given added information concerning the nature of postoperative pulmonary complications. He was particularly interested in those patients who, within 3 to 4 days after operation, developed fever, leucocytosis, cough, and purulent sputum. The types of pulmonary complications that these patients had could be divided into three main groups. The first were those with bronchopneumonia. The second group comprised patients having a massive collapse due

to an occlusion of a bronchus by exudate. The largest number of cases fell into the third group, and included patients having a purulent bronchitis with a low-grade bronchopneumonia (pneumonitis), sometimes in association with atelectasis due to occlusion of bronchi by exudate. King emphasized that a purulent bronchitis was the basic lesion in this third group of cases. Irons and Apfelbach have lately called attention to the pathogenesis of so called aspiration pneumonia. While the term has been frequently employed by clinicians for many years, the precise nature of the condition has not been carefully studied. Irons and Apfelbach assert that a characteristic type of pneumonia results from the aspiration of stomach contents during operation or shortly thereafter. Its features are hemorrhage, hyperemia, edema, and advanced post-mortem and retrogressive changes in the lungs. In acute cases, the bacterial flora of the stomach, lung, and bronchi are almost the same. The condition has been reproduced in dogs by the intratracheal introduction of stomach contents.

It is apparent that the pathogenesis of postoperative pneumonia is dependent upon several factors. Whipple has summarized some of the predisposing factors as follows: recent or concurrent inflammation of a part of the upper respiratory tract, pulmonary congestion, inhibition of normal respiratory movements or excursions as a result of abdominal incision, and debilitated states, such as sepsis and cachexia. Other important factors are the increased frequency of upper respiratory infections occurring during the winter and spring months, and a rise in the carrier rate of virulent pneumococci among the general population. The rôle of pulmonary congestion in the evolution of postoperative pneumonia must be stressed, because of its significance and because, in many instances, it can be prevented.

Since pneumococci of the higher types are frequently found in the nasopharynx of normal individuals, under certain operative and post operative conditions, these organisms may pass into the lower respiratory tract and cause an inflammatory reaction in the congested pulmonary tissue. Contributing factors are a diminution of the respiratory excursions and the cough reflex. Agencies responsible for pulmonary congestion in patients are the administration of excessive amounts of sodium chloride, and unreasonable quantities of fluids given intravenously both associated with cardiac failure.

Our clinical experience at the University Hospital has been similar to that expressed by King. We have found it very difficult to differentiate pneumonitis from atelectasis. This problem can be approached only on the basis of physical and x ray findings. Recognizing that a purulent bronchitis is the underlying lesion of both conditions, the physical findings of pneumonitis include dullness, increased tactile fremitus, increased bronchial breathing and whispered voice, and fine crackling rales. An x ray film of the chest may or may not reveal an increased area of density. If a bronchus becomes occluded by exudate the findings are those of atelectasis which are dullness, decreased tactile fremitus, and decreased breath sounds and whispered voice. X ray findings of considerable aid reveal an elevation of the diaphragm of the affected side, an increased area of density and in some instances, a shift of the mediastinum. However confusion arises many times because atelectasis may occur and then the bronchial exudate is coughed up without a simultaneous expansion of the collapsed lung. In this event there is the free passage of air into an area of atelectasis, and the physical findings closely approximate those of pneumonitis. Even an x ray film may not be helpful in the differentiation because the diaphragm may be elevated in both instances following an abdominal operation. Although King found that only about one-half of his cases of pneumonitis were accompanied by a demonstrable atelectasis, we have been unable to make a differentiation of our cases with the same degree of accuracy.

In summary then postoperative pneumonia is not a specific clinical entity. It may include patients having a typical lobar or lobular type of consolidation due, in most instances, to the pneumococcus. The mortality rate in this group of cases is high. The most common form involves those patients having a purulent bronchitis, which results in a low-grade type of pulmonary inflammation known as pneumonitis, or in atelectasis. A number of patients may have both atelectasis and pneumonitis. Considerable difficulty attends the differentiation of these two types. Finally there is a type described by Irons and Apfelbach called aspiration pneumonia.

We have endeavored to clarify the present status of the pathogenesis of postoperative pneumonia because of its direct bearing on the problem of therapy. It is not an easy task for the medical consultant to decide clinically whether he is being confronted with a patient who has a relatively benign lesion such as pneumonitis and/or atelectasis or who has the early manifestations of a lobar or lobular type of pneumococcal consolidation. Further more what may appear to be a benign process may progress to frank areas of consolidation and endanger the life of the patient. Therefore, for the protection of the patient every thing in the form of treatment should be carried out, and specific therapy if available should be instituted without delay.

Pneumococci of the higher types are usually found in the sputa of patients with post operative pneumonia. It is clearly recognized that these micro-organisms are often normal inhabitants of the nasopharynx and may have no etiological relationship with the pulmonary lesion. But when they are consistently encountered in large numbers in sputum, it may be reasonably assumed that there is a correlation. The problem is easily resolved when the more virulent pneumococci of lower types are present. It is only within the past few years that specific therapeutic agents have been available for use against the higher types of pneumococci. Type-specific antipneumococcal rabbit sera have been successfully employed. We have always been reluctant to use rabbit serum for these patients because of the danger of reactions in a seriously ill patient, and be

cause, in the majority of patients, the pulmonary infection has been relatively benign. The recent advances in chemotherapy have permitted a more successful application of specific agents in the treatment of all types of postoperative pulmonary infections, particularly those due to the pneumococci. While sulfapyridine has been used widely in the treatment of pneumonia, little data have been recorded in the literature concerning its value in the therapy of postoperative pneumonia. Hinshaw and Moersch administered sulfapyridine orally in 21 cases of postoperative pneumonia, and the patients responded as well as those with primary pneumonia. It is significant that half of the number of patients treated by them became nauseated because of the drug, and it was necessary to shorten the duration of sulfapyridine therapy in a number of others because of vomiting. We have had corresponding results in the treatment of many patients with postoperative pneumonia. In patients who were unable to take the drug by mouth, a solution of the sodium salt of sulfapyridine was administered intravenously with equally satisfactory results. However, when using sulfapyridine, one is constantly apprehensive concerning the harmful effect of the nausea and vomiting upon the operative wound of the patient as well as the added discomfort involved.

Sulfathiazole is a compound that has been used more recently in the treatment of pneumococcal pneumonia. Experimental and clinical data (1, 5, 6, 7, 9, 10) indicate that sulfathiazole is at least as effective as sulfapyridine upon the pneumococcus. During the past 6 months, we have used sulfathiazole and its sodium salt in the treatment of 40 patients with primary pneumococcal pneumonia, and the clinical results were equally as good as those obtained with sulfapyridine. Sulfathiazole had the added advantage in that it was followed much less frequently by nausea and vomiting. This latter observation has prompted the use of sulfathiazole and sodium sulfathiazole in the treatment of postoperative pneumonia in patients on the surgical services of the University Hospitals. The results have been highly satisfactory, and we desire to present observations that have been made

MATERIAL AND METHODS

A total of 22 patients was treated, including 15 males and 7 females. In all of the patients, clinical findings were elicited which fulfilled the criteria for a diagnosis of postoperative pneumonia. The patients have been divided into two groups. The first group, consisting of 6 patients, had bronchopneumonia with definite evidence of pulmonary consolidation. The 16 remaining patients had pneumonitis and atelectasis. The difficulties encountered in differentiating pneumonitis from atelectasis have already been recounted, and in the present group, we were unable to dissociate the two conditions. Therefore, we have classified this group as having pneumonitis and atelectasis. When available, sputa were examined bacteriologically, and typing for pneumococci was performed by the Neufeld method. Blood cultures were obtained before the institution of therapy with sulfathiazole.¹ An x-ray film of the chest was made as soon as the diagnosis of a pulmonary complication was considered. Bronchoscopy was performed upon one patient by Dr. Logan Leven in an attempt to remove an occluding plug of exudate from a bronchus. Sulfathiazole tablets were administered orally whenever possible. The initial dose was 2 to 4 grams, and then 1 gram every 4 hours for approximately 5 days. When the drug was given for a longer period, the doses were reduced. Sodium bicarbonate was administered along with sulfathiazole to only 4 patients. It appears very doubtful whether it is necessary to use the alkali in conjunction with sulfathiazole. There were 12 patients who were unable to take any medication orally, and a solution of the sodium salt of sulfathiazole was given intravenously. A 5 per cent solution in warm sterile distilled water was used. The initial dose was 2 to 3 grams (40 to 60 cc m) and then 1 gram (20 cc m) every 8 hours. As soon as possible, 1 gram of the sulfathiazole tablets was given orally every 4 hours. The concentrations of both the free and conjugated forms in the blood were determined by the method of Bratton and Marshall, using the Evelyn

¹The bacteriological studies were performed by Dr. M. V. Novak and Dr. M. Levine of the Bacteriological Laboratories of the University Hospitals.

photoelectric colorimeter. Careful observations were made for toxic reactions to the drug.²

RESULTS

Pertinent clinical data concerning the patients having bronchopneumonia are shown in Table I. All of the patients recovered. Pneumococci were not recovered from the blood streams of any of the patients in either group. Following the administration of sulfathiazole, the fever subsided and there was definite clinical improvement within 24 hours. A solution of sodium sulfathiazole was given intravenously to 3 of the 6 patients. It is of interest to note the concentrations of sulfathiazole attained in Case 6. Twenty minutes after 3 grams of sodium sulfathiazole had been given

the blood level of free sulfathiazole was 24.8 milligrams per 100 cubic centimeters. There were 1.3 milligrams present as the conjugated form. Twelve hours later 1 gram of the salt was administered and twenty minutes later the blood concentration of free sulfathiazole was 15.2 milligrams per 100 cubic centimeters and the level of the conjugated form was 2 milligrams.

The results in the larger group of patients having pneumonia and atelectasis are presented in Table II. The clinical response in this group was also quite definite coincident with the administration of sulfathiazole. There was a decline in temperature and in none of the patients was there a progression of the pulmonary lesion. Two patients in this group expired from complications unrelated to their pulmonary infections or sulfathiazole therapy. Ten of the patients received the sodium salt intravenously. One patient (Case 5) had been given a total of 5 grams of sulfapyridine by mouth following which she experienced an episode of severe vomiting. When the vomit

^aMore recently we have treated a group of patients by administering solutions of sodium sulfathiazole subcutaneously. Depending upon the severity of the patient, doses from 2 to 3 grams of the sodium salt are dissolved in 100 cc. of physiological saline solution (a 10% free salt concentration of sodium sulfathiazole). The fever by hypodermoclysis is at the rate of about one to two cubic centimeters per hour. They can maintain an adequate blood concentration of sulfathiazole and be maintained for 24 hours or more. T. Shuman, personal communication. The concentrations of sodium sulfathiazole are given intravenously at the same time the subcutaneous administration started.

ing had subsided sodium sulfathiazole was given intravenously with no untoward effects.

It is difficult to state at the present time what is the desirable blood concentration of sulfathiazole for the treatment of patients with postoperative pneumonia. Satisfactory clinical results were obtained in the present series with levels of free sulfathiazole from 3 to 5 milligrams per 100 cubic centimeters of blood.

The toxic manifestations from sulfathiazole were less than those encountered following the use of sulfapyridine. Smaller amounts of the circulating sulfathiazole were present as the conjugated form as compared to sulfapyridine. Four of the patients complained of nausea during the course of treatment, but in none was it severe enough to necessitate withdrawal of the drug. One patient developed a gross hematurlia without other evidence of impaired renal function. In 1 individual an erythema nodosum-like eruption appeared on the extremities after 8 days of sulfathiazole. The lesions subsided when sulfathiazole therapy was stopped.

VALUE OF SULFATHIAZOLE THERAPY

We do not desire to imply that the recovery of the patients in this series was due entirely to the use of sulfathiazole. Conclusions concerning the therapeutic effectiveness of the drug can be based only upon the results obtained in a much larger series of cases. The important point that we wish to make is since it is often exceedingly difficult to make a clinical distinction between an early lobar or lobular pneumonia and pneumonitis and/or atelectasis in an acutely ill patient, sulfathiazole is a specific antipneumococcal agent that may be given with a reasonable degree of safety. At the present time, we do not hesitate to administer the drug to any patient with a relatively benign pulmonary infection but in whom a number of other factors have reduced his resistance so that a progression of the lesion would tip the balance against his recovery. Sulfathiazole is of especial value in the therapy of postoperative pneumonia in that it may be readily administered intravenously in the form of sodium sulfathiazole.

SUMMARY

1 The term postoperative pneumonia is applied to patients having a lobular or lobar type of consolidation, or a purulent bronchitis with a low-grade type of parenchymal inflammation usually accompanied by atelectasis. The pneumococcus is the etiologic agent in the majority of cases.

2 Twenty-two patients with postoperative pneumonia were treated with sulfathiazole and/or sodium sulfathiazole with satisfactory clinical results.

3 Since sulfathiazole causes less nausea and vomiting and appears to be equally as effective for pneumococcal pulmonary infections as sulfapyridine it is recommended that sulfathiazole or sodium sulfathiazole should be used in the treatment of postoperative pneumonia.

SULFONE CHEMOTHERAPY IN HEMATOGENOUS OSTEOMYELITIS

EDGAR BICK, M D , F A C S , New York, New York

THE prognosis of any single case of acute osteomyelitis depends on many variable factors. Some of these, such as the time and extent of operation, and the type of after-care, can to a great extent be controlled by the surgeon, others, such as the strain and virulence of invading organisms, the previous medical condition of the patient, his powers of resistance, and the intensity of the local tissue reaction, are altogether beyond his control. Therefore, in considering the effect of any procedure on the course of the disease, one must attempt to evaluate that procedure by reasonably simple and tangible criteria. With this premise in mind, 20 cases of hematogenous osteomyelitis were reviewed in which chemotherapy with sulfone derivatives was used as part of the treatment. Aside from the use of these drugs, the patients were treated no differently than were other patients with similar conditions before the introduction of the drugs or, in a number of instances, concurrently. From time to time different types of bone excision have been used, such as drill holes, cortical windows or bone wedges, but in all instances the general approach of establishing adequate drainage at the optimal time, followed by the Orr treatment or a modification thereof to suit the individual case, was carried out.

The present series while not large represents 3 years of experience with carefully studied cases. During this period the drugs have been used on many more cases, such as secondarily infected wounds, which were not included in the investigation. To the writer's knowledge, no comparable series has as yet been reported. Mitchell, in 1938, published his results in 5 cases of *Staphylococcus aureus* osteomyelitis treated by uleron (Bayer's sulfanilamide), Weidekamp, in the same year, discussed the use of prontosil in tuberculous and non-tuberculous osteomyelitis, including 1 case

of the latter. Many of the recent papers which review the general subject of the clinical use of sulfone derivatives, mention their application to osteomyelitis without discussing their effect on the course of the disease other than the control of general sepsis.

The effect of sulfone chemotherapy on general sepsis in streptococcus and staphylococcus infections is being adequately studied by many investigators and its present value is fairly well established. Likewise the pathology and general course of osteomyelitis has been thoroughly described by Lexer, Wilensky (9), Key, Phemister, Brown, and many others, and also requires no further discussion at this time. For present purposes the objective has been limited to a study of the effect of sulfone chemotherapy added to standard surgical procedures on (1) the course of the local bone pathological process, (2) on recurrence, and (3) on metastases. It is common knowledge among those who have watched the natural course of the disease that the establishment of drainage, even early in the disease, does not necessarily prevent the progressive involvement of bone over a more or less limited area of the adjacent shaft. This is easily demonstrated by a series of x-ray films taken during the postoperative period. In successful cases, this area gradually regains its normal appearance. In widespread lesions, the reorganization of bone structure in healed cases may not be completely normal in structure, but still consists of well established trabeculae and canals. If the addition of sulfone medication to the treatment could be shown either to eliminate or significantly retard this cycle of postoperative necrosis in a large percentage of cases, then its effect on the local infection would be demonstrated. If cases so treated showed a considerable decrease in recurrences or in metastases, its value would be evident. The cases in this series were analyzed with these criteria in mind.

From the Orthopaedic Service Mt Sinai Hospital

Chart 1. Temperature levels. x start of use of drug I II III sulfanilamide
S sulfapyridine

In the earlier cases of this series, as in Mitchell's cases, sulfanilamide was used for both staphylococcal and streptococcal infections. As the derivative sulfapyridine and later sulfathiazole appeared these were used on staphylococcal cases, and sulfanilamide was reserved for the beta hemolytic streptococcus. In several instances combinations running either simultaneously or in sequence were used. In general it may be stated here that in the earlier cases in which sulfanilamide was used in staphylococcal osteomyelitis, patients recovered in a manner very similar to that of later cases. There was the same drop in temperature the same cycle of bone involvement, and the same general recovery. These cases resembled those reported by Mitchell. The present series shows the usual variety of age duration location operative time and other factors as would be found in any current or preceding series. In discussing these cases the significant facts will be mentioned at some length. The corroborating details can be studied only by examining the data of the individual cases summarized.

EFFECT ON TEMPERATURE

One of the dramatic manifestations of the use of sulfone derivatives in the various infec-

tions has been the sudden drop in temperature which frequently follows. This is especially remarkable in such infections as pneumonia, streptococcal sore throat, and meningitis. Chart 1 shows a composite picture of 6 characteristic temperature charts. Reference to similar charts published by Wilensky (10) on patients treated without sulfone medication, and confirmed by our own charts in similar cases demonstrates no significant alteration. In most instances, following the establishment of drainage in uncomplicated cases the temperature does drop from a relatively high level to a lower. Occasionally the drop is to normal in a few days usually it falls to between 100-101 degrees and gradually subsides to normal in a week or two in the less extensive infections, or in a longer period in the more widespread cases. In the present series, the temperature readings did not as a group deviate from groups in which sulfone chemotherapy was not used. The temperature readings varied with the local infection and its surgical aspects, that is, drainage area of infection and intensity of tissue reaction. In several streptococcal cases in which patients were not operated upon the temperature fell soon after the application of a plaster-of-Paris bandage and the customary dose of sulfanilamide given

by mouth, but not more rapidly than has occurred in similar cases in which patients were treated only by plaster

WOUND HEALING TIME

The length of time of healing of the operative wound in these cases was not noticeably shortened. Here again it varied with the customary rules of surgical practice, that is, the extent of wound surface, and persistence of drainage. There was no noticeable difference in the quality or quantity of granulation tissue.

BONE NECROSIS

This phenomenon was studied in some detail. Figures 1 to 3 show characteristic cycles in several of the cases which were adequately drained at an optimal time. The patients were relieved after operation and by all the customary objective and subjective observations went through the usual course of an uneventful recovery from acute hematogenous osteomyelitis. Sulfone therapy did not to any measurable degree retard or restrain the completion of the cycle of bone absorption and restoration in these cases. There were 7 such cases in the present series. A number of cases, especially in the younger age group, recovered without bone changes, after simple incision of subperiosteal abscesses. These cases followed the course and time elements of such patients treated similarly without sulfone chemotherapy.

RECURRENCES

Recurrence in this study refers to local reactivation of a clinically healed lesion as distinct from an exacerbation of an unhealed area, or the late appearance of a metastatic focus. In this series there have already been two recurrences, both in staphylococcal infections. In neither case was the recurrence operated upon. In one instance it subsided in a week with wet dressings and sulfapyridine, in the other, wet dressings were enough. The latter was, on his first admission for sulfone therapy, an acute recurrence of an old osteomyelitis. The infection was not eradicated by the drug.

METASTASES

Metastatic foci were observed during the period of treatment or soon thereafter in 2

cases. Here again the percentage is about the same as in larger series treated without sulfone derivatives. In one very active staphylococcal infection, with severe septicemia, involving primarily the clavicle, there were metastases to both humeri, and the left tibia. There was also a widespread papulopustular skin eruption (3). In another staphylococcal infection of the femur, secondary foci appeared about the ankle and alveolar process.

TOXIC MANIFESTATIONS

In one of the earliest cases in which sulfapyridine was used the patient died of a typical agranulocytosis. The drug was given for 5 days beginning on the day of admission, which was also the day of operation. On the fifth day, temperature was normal, and the patient in excellent condition. It was decided to continue the drug in the hope of definitely eliminating the staphylococcal infection. Five days later, the white blood count was still 10,600, 2 days later it had dropped to 4,000, with 72 per cent polymorphonuclears. The drug was stopped. Next day the count was 3,400 cells, 24 per cent polymorphonuclears. Six days later, during which period daily transfusions and full doses of pentonucleotide were given, the white count fell to less than 300 cells, all of which were lymphocytes, and the patient died. In all, the patient had been given 93 grams of sulfapyridine between March 28 and April 13. This case has been reported in detail elsewhere (7). Aside from this instance there were no other serious toxic manifestations. In several cases the drug was stopped because of nausea or excessive blueness. The latter symptom is no longer dreaded as at first, but marked nausea is still taken seriously.

BLOOD CULTURES

In 7 cases the blood showed *Staphylococcus aureus* on culture, in 2 cases, *Streptococcus haemolyticus* appeared. In 2 cases both of these organisms appeared together, and in 9 cases the blood showed no organisms at all. In all but 1 case showing positive blood cultures, these were sterile from 2 to 5 days after the institution of treatment, regardless of the state of healing of the local infection. The only case in which the blood cultures re-

maintained positive for a considerably longer period was in the patient who suffered multiple metastases and the generalized pustular eruption.

ANALYSIS OF RESULTS

All the cases were treated according to standard surgical indications. The addition of sulfone chemotherapy was supplementary. Of the 3 patients not operated upon 1 showed *Streptococcus haemolyticus* in the blood stream, the blood cultures of the 2 others were negative. One case involved the pubis, another the edge of the astragalus and the third was an acute recurrence of an old osteomyelitis of the femur without sequestrum. All 3 of these patients would have been handled similarly even without chemotherapy and compared to similar cases the condition might well have subsided without operation. Whether the outcome was influenced by the sulfone therapy employed is conjectural, but the length of time involved in their resolution as compared to that in similar cases in which patients were treated conservatively without the use of such drugs was not markedly altered. In uncomplicated cases in which the condition subsided shortly after operation, no treatment was used other than surgical after care. In cases in which the infection did not subside promptly blood transfusions were given freely. In several severe cases of staphylococemia, along with sulfone therapy staphylococcal antitoxin was used in large amounts. It must be noted that had these infections responded to the drug the prolonged use of additional forms of therapy would not have been indicated.

However it is necessary to remark on certain phases of sulfone therapy in connection with this problem in order not to present a too one-sided observation. Unquestionably the instances of acute osteomyelitis following ear nose and throat infections have been decreased since the sulfone drugs have been used in their treatment. Furthermore those patients whose local lesions do not subside promptly after operation do not present the characteristic general septic appearance that was so often seen in past years. The bacteremia can unquestionably be controlled during this period. However it must be

noted, that, after the drug is stopped, the local focus, if it persists, can still be the source of metastases. Furthermore it cannot be disproved that certain of the metastases occurred even during the time the drug was used. Temperature levels are kept at a lower plane during the acute febrile state when sulfone therapy is used. It is important to recognize this fact to avoid neglecting still undrained areas. In several instances, a temperature level would rise during a period when the drug was withheld, and fall to a lower level when it was again used, thus indicating a specific antipyretic action.

SUMMARY OF CASE HISTORIES

CASE 1: Male aged 7 years, was admitted to the hospital February 3, 1930, because of pain near the left ankle, of 6 days duration. Wet dressings were applied. From February 1 to 5, 16 grams of sulfanilamide were given. On February 13, subperiosteal abscess over the lower end of the tibia, as incised and packed with vasoline gauze. On February 15, 370 cubic centimeters whole blood transfusion was given. Blood culture on February 13 showed *Staphylococcus aureus*. February 14, hemoglobin was 58 per cent; red blood cells numbered 3,650,000; white blood cells, 3,300. February 16, hemoglobin was 7 per cent. March 6, hemoglobin was 76 per cent; red blood cells, 4,470,000; white blood cells, 9,500.

Patient was readmitted on March 6, 1930, at which time there was a recurrence of tenderness and swelling at the ankle. The wound had healed. Temperature was 1 degree but subsided with administration of wet dressings and the administration of sulfapyridine (1 gram) were given from March 8 to 9.

CASE 2: Male, aged 1 year, as admitted to the hospital February 3, 1930, with pain in the right knee for 4 days. He had fever. X-rays films showed early cortical bone lesion at the metaphysis of the tibia. On February 5, subperiosteal abscess as incised and packed. From February 4 to 7, 30 grams of sulfanilamide were given. On February 3, hemoglobin was 60 per cent; white blood cells, 2,700. February 17, hemoglobin was 60 per cent; white blood cells, 7,600. March, hemoglobin 25.67 per cent. February 1, 500 cubic centimeter blood transfusion was given. Blood culture on February 3 showed *Staphylococcus aureus*. On February 5 it was sterile.

On March 3, patient was discharged with a draining sinus. On July 3, 1930, the wound was finally healed. During the time of treatment, serial X-ray films showed an increase in the area of bone involvement through the upper fourth of the tibia shaft, followed by gradual regeneration and increased density of bone substance.

Fig 1 Case 7 Left above, before operation, and left below and right, 2 months after operation

CASE 3 Female, aged 66 years, was admitted to hospital February 7, 1938, for pain in the upper end of the tibia, duration, 1 month. Nineteen years previously patient had been operated on for a bone abscess in this area but had remained symptom-free ever since. February 16, a cortical window was removed at the level of the lesion in the upper end of the tibia. From February 21 to 26, 10 grams of sulfanilamide were given. On March 18, a plastic closure of the wound was performed. Hemoglobin remained around 80 per cent during hospital stay. Blood culture showed *Streptococcus hemolyticus* β . Before discharge in April, 1938, the wound had reopened and was draining.

CASE 4 Male, aged 1½ years, was admitted to the hospital April 13, 1939, with pain in the right wrist and with fever and malaise of 1 day's duration. On April 15, a subperiosteal abscess over the lower end of the right radius was incised and packed. On April 22, the operative incision was enlarged and repacked. From April 15 to 23, 16 grams of sulfanilamide were given. From April 20 to May 6, 32 grams of sulfapyridine were given (from April 20 through the 23rd, both were given concurrently). During this time 10 transfusions of 250 to 500 cubic centimeters each were given, 300,000 units of staphylococcus antitoxin, 40 cubic centimeters of scarletinal convalescent serum, and large amounts of intravenous glucose and calcium. On April 13, white blood cells numbered 23,000, April 17, white

blood cells, 6,000, April 18, white blood cells, 4,500, with normal differential. April 28, white blood cells numbered 3,400. Blood culture showed *Staphylococcus aureus* α , and *Streptococcus hemolyticus* β .

Patient was readmitted on August 19, 1939, with a draining sinus and rise in temperature. He was discharged with subsidence of symptoms. On March 28, 1940, the patient was readmitted because of extensive bone necrosis of the lower two-thirds of the radius. A diaphysectomy was performed and a bone transplant inserted.

CASE 5 Male, aged 9 years, was admitted to the hospital April 26, 1940, with pain in the groin, of duration of 8 days. He had fever. X-ray films showed an osteomyelitic lesion in the right pubis. From April 29 to May 2, 13 grams of sulfanilamide were given. From May 2 to 9, 27 grams of sulfathiazole were given. On April 26, hemoglobin was 75 per cent, white blood cells, 14,500, sedimentation rate, 22 minutes. Blood culture was negative. In September, 1940, x-ray films showed some localized process in the pubis with evident regeneration of bone in that area.

CASE 6 Female, aged 58 years, was admitted to the hospital on September 9, 1939, with osteomyelitis of the femur. Symptoms had been present for 3 weeks. This was an acute recurrence of an old symptom-free osteomyelitis. Wet dressings were applied, and 10 grams of sulfapyridine were given from September 9 to September 12. Wound culture showed

Fig. 4. Case 4. Pre-operative, postoperative and healed.

Staphylococcus aureus and Hemoglobin on September 9 was 94 per cent. white blood cells, 8,500, with normal differential. Symptoms subsided and patient was discharged. Three weeks later there was a similar recurrence which subsided under wet dressings without the use of sulfone drugs. Patient has been symptom free ever since.

CASE 7. Female aged 3 years, was admitted to the hospital on March 4, 1939, with osteomyelitis of the humerus duration of symptoms, 4 days. Initial x-ray films showed faint haziness about the upper metaphysis. On the day of admission, subperiosteal incision was packed with vaseline gauze after it was incised. Seventy-two grams of sulfapyridine were given from March 4 to March 7. Blood culture showed *Staphylococcus aureus* on March 5 and was negative on March 15. On March 4, the white blood cell count was 12,000 hemoglobin, 65 per cent. On March 15 the white blood cell count was 8,400 hemoglobin 66 per cent. On March 3, the white blood cell count was 8,600 hemoglobin 60 per cent. On March 8, the hemoglobin was 58 per cent, and a transfusion of 35 cubic centimeters of blood was given. Serial x-ray films taken during the stay at the hospital showed progressive destruction of the upper third of the humerus. Patient was readmitted to the hospital on November 7, 1939, with two draining sinuses. On the following day, sequesterectomy was removed. On April 3, 1940, the patient still presented the draining sinuses. X-ray films showed increasing density of the lesion in the bone.

CASE 8. Female aged 3 years was admitted to the hospital on August 1, 1939, with pain in her chest 1 day duration. X-ray examination re-

vealed osteomyelitis of a rib. From August 3 to August 5, grams of sulfapyridine were given. On August 29 the bone incision was incised and packed. Wound culture showed *Staphylococcus aureus* and *Streptococcus hemolyticus* β . Hemoglobin on August 29 was 92 per cent. white blood cells, 7,700. On August 30 hemoglobin was 84 per cent. Blood culture was negative. Ten months later the wound was still draining and the x-ray showed no change in the local lesion.

CASE 9. Male aged 4 years, was admitted to the hospital on August 4, 1939, with osteomyelitis of the sternum duration of symptoms, 4 days. Ten to four grams of sulfapyridine were given from August 4 to August 5. On August 7 the lesion in the sternum was incised and drained. Blood culture showed *Staphylococcus aureus* and *Streptococcus hemolyticus* β . On August 4 the hemoglobin was 95 per cent. red blood cells numbered 5,000,000 white blood cells, 20,000 sedimentation rate as 35 hours. On August 6 the white blood cells numbered 8,000. On December 4, 1939, the wound was entirely healed.

CASE 10. Male aged 8 years was admitted to the hospital on July 7, 1939, with osteomyelitis of the fibula duration of symptoms, 2 weeks. This was a recurrence of a lesion about 20 years previously and asymptomatic since that time. On July 18, diaphysectomy was performed. From July 9 to July 16, grams of sulfanilamide were given. Hemoglobin as maintained between 55 and 65 per cent during the hospital stay. On August 8, 500 cubic centimeter blood transfusion was given. Wound culture showed *Staphylococcus aureus*. Following the operation, the wound drained. The temperature remained at 100 degree level for over month.

CASE 11. Male aged 33 years, was admitted to the hospital on March 27, 1939, with pain about the hip duration of symptoms, 2 weeks. A diagnosis of osteomyelitis involving the ileum and upper end of the femur was confirmed by the x-ray. On March 30, the bone lesion was incised and packed. From March 27 to April 1, grams of sulfanilamide were given. The bone incision was further extended on April 17 because of persistent drainage. Blood culture was negative and wound culture showed *Staphylococcus aureus*. On admission the patient was acutely ill with temperature of 104 degrees F. This fell after the first operation but rose to 103 degrees F. a week later and continued to rise and fall till the second operation was performed. On March 7 hemoglobin was 7 per cent. white blood cells, 9,700. On April hemoglobin was 64 per cent. white blood cells 9,700. The wound as still draining at the time of discharge and there was no signs months later of bony regeneration.

CASE 12. Male, aged 6 years was admitted to the hospital on March 18, 1939, with osteomyelitis of the upper end of the humerus. Duration of symptoms was 3 days. On the day of admission, the bone was incised and the wound packed. Blood cul-

ture on March 28 showed *Staphylococcus aureus* α and was negative on April 2. One hundred and ninety-three grams of sulfapyridine were given. On March 28, the hemoglobin was 95 per cent, white blood cells, 16,700. On March 30, white blood cells numbered 11,000. On April 5, white blood cells numbered 11,800. On April 10, the white blood cells were 10,600. On April 12, the cell count had dropped to 4,000, with 72 per cent polymorphonuclears, and on April 14 to 3,400, with 24 per cent polymorphonuclears. On April 19, the white blood cells were counted below 300 with 100 per cent lymphocytes. Beginning on April 14, blood transfusions of from 250 to 500 cubic centimeters were given daily and 10 cubic centimeters of pentonucleotide were given four times a day. Patient died on April 20, 1939.

CASE 13 (3). Male, aged 12 years, was admitted to the hospital on December 16, 1938, with osteomyelitis of the clavicle, duration of symptoms, 3 days. The bone lesion was incised and packed on the day of admission. Patient reacted badly, with prolonged high temperatures. From December 17, 1938, to January 20, 1939, 142 grams of sulfapyridine were given. Blood culture showed *Staphylococcus aureus* α (70 colonies per c cm). Patient developed a generalized pustular eruption during the postoperative period, with metastases in both humeri and the left tibia. These metastases subsided with wet dressings. During the course of the illness, x-ray films showed progressive destruction in the primary bone focus and the metastases. During this period, in addition to sulfapyridine, 90,000 units of staphylococcus antitoxin were given, as well as a total of 2,750 cubic centimeters of blood. On December 16, 1938, the white blood cells numbered 8,000. During the acute illness the number rose to 23,000, and toward the end fell to 4,000. Patient was finally discharged with all wounds healed. To date, x-ray films have showed progressive regeneration of the bone lesions.

CASE 14. Male, aged 12 years, was admitted to the hospital on June 21, 1938, with osteomyelitis of the ulna, duration of symptoms, 3 days. A subperiosteal abscess over the ulna was incised and packed on June 27, 1938. Wound culture showed *Staphylococcus aureus* α . Blood culture was negative. The x-ray films taken on admission showed no signs of bone involvement. The wound continued to drain. On July 25, x-ray films showed extensive osteomyelitis of the ulna. On July 27, two thirds of the ulna was resected, the bone was boiled according to the technique of Orell, and reimplanted. On October 14, 1938, part of the reimplanted bone which had formed a sequestrum was removed. The wound continued to drain through sinuses for many months. On March 28, 1940, the wounds were healed. X-ray films showed no union between the remaining bone implant and the residual of the ulnar.

CASE 15. Male, aged 75 years, was admitted to the hospital on October 22, 1938, with osteomyelitis

Fig 3 Case 13 Roentgenograms taken before operation, 2 weeks after, and later showing metastasis to humerus

of the humerus, duration of symptoms, 1 month. The bone was incised and packed on October 22. From October 23 to October 27, 9 grams of sulfanilamide were given, since the wound culture showed *Staphylococcus aureus* α . Blood culture was negative. The patient developed bronchopneumonia and died on October 28, 1938.

CASE 16. Male, aged 12 years, was admitted to the hospital on March 2, 1938, with osteomyelitis of the femur, duration of symptoms, 6 days. On March 3, a subperiosteal abscess over the lower end of the femur was incised and packed. Wound culture showed *Staphylococcus aureus* α . From March 2 to March 4, 7 grams of sulfanilamide were given. In spite of that, the temperature remained high. On March 2, hemoglobin was 80 per cent, red blood cells, 5,000,000, and white blood cells, 17,000. On March 4, the number of white blood cells dropped precipitately to 5,150. *Staphylococcus* antitoxin, 27,000 units, as given the next day, as well as a blood transfusion of 900 cubic centimeters. During the postoperative period, the patient developed infectious metastases over the right fibula and in the alveolar process. The alveolar process was relieved

Fig. 2. Case 4. Pre-operative, postoperative and healed.

Staphylococcus aureus. Hemoglobin on September 9 was 94 per cent, white blood cells, 8,500, with abnormal differential. Symptoms subsided and patient was discharged. Three weeks later there was a similar recurrence which subsided under wet dressings without the use of sulfon drugs. Patient has been symptom-free ever since.

Case 7. Female, aged 7 years, was admitted to the hospital on March 4, 1939, with osteomyelitis of the humerus of duration of symptoms 4 days. Initial ray films showed faint haziness about the upper metaphysis. On the day of admission, a subperiosteal incision was packed with vaselin gauze after it was incised. Seventy-two grams of sulfapyridine were given from March 4 to March 7. Blood culture showed *Staphylococcus aureus* on March 5 and as again on March 5. On March 4, the white blood cell count was 10,000 hemoglobin, 65 per cent. On March 6, the white blood cell count was 8,400 hemoglobin 6 per cent. On March 3, the white blood cell count was 8,600 hemoglobin 50 per cent. On March 8 the hemoglobin was 58 per cent and transfusion of 35 cubic centimeters of blood was given. Serial ray films taken during the stay in the hospital showed progressive destruction of the upper third of the humerus. Patient was readmitted to the hospital on November 7, 1939, with two draining sinuses. On the following day, sequestrum was removed. On April 3, 1940 the patient still presented two draining sinuses. Ray films showed increasing density of the lesion in the bone.

Case 8. Female aged 3 years, was admitted to the hospital on August 1, 1939, with pain in her chest of 4 days duration. X-ray examination re-

vealed osteomyelitis of ribs. From August 3 to August 5, 1 gram of sulfapyridine was given. On August 20 the bone abscess was incised and packed. Wound culture also showed *Staphylococcus aureus* and *Streptococcus hemolyticus* β . Hemoglobin on August 1 was 9 per cent, but blood cells, 7,300. On August 30 hemoglobin was 28 per cent. Blood culture was negative. Ten months later the wound was still draining and the x-ray also showed no change in the local lesion.

Case 9. Male, aged 3 years, was admitted to the hospital on August 14, 1939, with osteomyelitis of the tibia of duration of symptoms, 4 days. Ten grams of sulfapyridine were given from August 14 to August 15. On August 17 the lesion in the tibia was incised and drained. Blood culture showed *Staphylococcus aureus* and *Streptococcus hemolyticus* β . On August 14, the hemoglobin was 95 per cent, red blood cells numbered 5,500,000, white blood cells 30,000, sedimentation rate 35 hours. On August 6 the white blood cell number was 8,000. On December 14, 1939, the wound was entirely healed.

Case 10. Male, aged 8 years, was admitted to the hospital on July 7, 1939, with osteomyelitis of the fibula of duration of symptoms, 1 week. This was recurrence of a lesion which 30 years previously had asymptomatic since that time. On July 18, diaphysectomy was performed. From July 9 to July 16, 6 grams of sulfanilamide were given. Hemoglobin as maintained between 55 and 65 per cent during the hospital stay. On August 18, a 500 cubic centimeter blood transfusion was given. Wound culture showed *Staphylococcus aureus*. Following the operation, the wound drained. The temperature persisted at 100 degree level for over month.

Case 11. Male, aged 33 years, was admitted to the hospital on March 27, 1939, with pain about the hip of duration of symptoms, 2 weeks. A diagnosis of osteomyelitis involving the femur and upper end of the femur was confirmed by the x-ray. On March 30, the bone lesion was incised and packed. From March 27 to April 1, 10 grams of sulfanilamide were given. The bone incision was further extended on April 7 because of persistent drainage. Blood culture was negative and wound culture showed *Staphylococcus aureus*. On admission, the patient was acutely ill with temperature of 104 degrees F. This fell after the first operation but rose to 103.6 degrees F. A week later and continued to rise and fall till the second operation was performed. On March 27 hemoglobin was 7 per cent, white blood cells, 9,700. On April 1 hemoglobin was 64 per cent, white blood cells, 9,700. The wound was still draining at the time of discharge and there was no sign 6 months later of any bone regeneration.

Case 12. Male, aged 12 years, was admitted to the hospital on March 8, 1939, with osteomyelitis of the upper end of the humerus. Duration of symptoms was 3 days. On the day of admission, the bone was incised and the wound was packed. Blood cul-

EXPERIMENTAL COLLATERAL CIRCULATION OF THE HEART

KARL FRIEDBACHER, M D , F A C S , West Allis, Wisconsin

ALERT surgeons in their endeavor to relieve Pick's disease by removing constricting pericardial adhesions encountered blood vessels of considerable size traversing between the myocardium and the adhesions (1) This observation led to the belief that possibly a new blood supply to the heart could be produced by surgically grafting various tissues to the heart Consequently, skeletal muscle, omentum, fat, mediastinal tissue, lung, etc were implanted on the heart and, in some instances, vascular connections were demonstrated (2) The most recent of these works is that of H B Burchell who concludes "The possibility that small vascular connections between a graft and the heart might develop to a functioning degree cannot be denied, but in experiments seemingly favorable to such a result it has not occurred"

The natural processes of life bring about the narrowing of the lumina of the coronary vessels and too frequently early dire results are not readily produced in experimental animals Acute and chronic mechanical constrictions of these arteries have been made in the laboratory and the ensuing infarct, degeneration, and thinning of the myocardium and papillary muscles have been observed To offset this pathological process various grafts were implanted on the experimental heart with the hope that new blood vessels large enough to carry sufficient blood would develop to nourish the ischemic areas One must with reservation compare this condition produced in animals having young healthy hearts, adequately nourished and possessing the physiological means of repair and construction, to the human suffering from coronary sclerosis who has none of these in such abundance Nevertheless on the basis of careful experimental work of this nature, surgeons have attempted and with some measure of success treated these diseased hearts I refer

particularly to Beck (3) in this country and O'Shaughnessy of London, England The former prefers to use the pectoralis major muscle and the latter the omentum as the tissue of choice for grafting

The writer in a series of experiments has taken the omentum, intercostal muscles, lung, and internal mammary artery as grafts and after an interval of 3 to 6 weeks, partially interrupted the flow of blood through the main branches of both coronary arteries Electrocardiograms revealed recent infarcts and then, as time went on, a gradual improvement appeared until the tracings approached those of a normal animal The question which arises resolves itself into two distinct problems Has the graft contributed to the healing process by delivering blood to the heart or have the normally present anastomoses enlarged and carried the necessary nourishment? It is a known fact that a considerable communication between right and left coronary arteries exists especially at the apex and that numerous anastomoses are present at the bases of the great vessels between pericardial and coronary vessels

Fig 1 A, coronary artery, B, internal mammary artery

by dental surgery and the fibular process subided with wet dressings.

Cas 7. Male, aged 35 years was admitted to the hospital on September 3, 1938 with osteomyelitis of the upper end of the humerus duration of symptoms 5 days. On September 4, bone section was removed to the site of lesion and the wound was packed. Seventy-five cubic centimeters of sulfanilamide were given intravenously in repeated doses on September 3 and 4. The hemoglobin came about 85 per cent from September 3 to September 5 with two intervening examinations. A blood transfusion of 500 cubic centimeters was given during the postoperative period. Blood culture on September 3 showed *Staphylococcus aureus*, and on September 6 was sterile. During the postoperative period, in spite of immobilization, bone involvement as shown by x-ray studies extended throughout the upper third of the humerus. The wound subsequently healed and later x-ray films have shown increasing regeneration within the lesion.

Cas 18. Female, aged 4 years, was admitted to the hospital on January 4, 1938 with osteomyelitis of the lower end of the femur duration of symptoms 5 days. X-ray films were negative concerning any bone involvement at this time. A subperiosteal abscess was incised and packed on January 4. On January 5, 4.5 grams of sulfanilamide were given. Hemoglobin varied from 65 to 70 per cent during the hospital stay. A blood transfusion of 500 cubic centimeters was given. Blood culture was negative, and the wound culture showed *Staphylococcus aureus*. During the postoperative period, serial x-ray films showed progressive bone involvement. The wound healed and subsequent x-ray examination showed gradual regeneration of the bone.

Cas 9. Male, aged 15½ years was admitted to the hospital on July 3, 1937 with osteomyelitis of the femur duration of symptoms 4 days. In this case 5 grams of sulfanilamide were given between July 8 and July 15. Blood culture was negative. The temperature remained elevated to 104 degrees F. during the early period of sulfone therapy. On July 3, the bone was incised and packed after which the temperature dropped to almost normal within 3 days. Wound culture showed *Staphylococcus albus*. On July 7 the hemoglobin was 50 per cent and the white blood cells 9,000. On July 13 the hemoglobin was 78 per cent and the white blood cells 7,700, showing toxic granules. On July 6 the hemoglobin was 76 per cent and the white blood cells 4,800. X-ray films showed postoperative extension of the area of bone involvement. The wound subsequently healed and has remained quiescent. Later x-ray examination showed progressive bone regeneration.

Cas 20. Female, aged 3½ years, was admitted to the hospital on May 1940 with osteomyelitis of the posterior region of the tibia duration of symptoms

5 days. An operation was performed from May 3 to May 7. 4.3 grams of sulfanilamide were given. Blood concentration of sulfanilamide on May 14 was 4 milligram per 100 cubic centimeters. A plaster boot was applied. Blood culture on May 14 showed *Streptococcus hemolyticus* a sterile on May 4, and again sterile on July 6. Serial x-ray films showed cycle of bone regeneration. Patient has had no recurrence since that time.

CONCLUSION

On the basis of 20 cases of hematogenous osteomyelitis, and until the above observations are invalidated by a larger series, the following conclusions are presented.

1. The addition of sulfanilamide or sulapyridine to the treatment of hematogenous osteomyelitis has not significantly altered the general course of bone pathology rate of recurrences, or metastases.

2. In a series of 20 cases representing all degrees of severity, there was only 1 death and that due directly to sulapyridine. In several instances toxicity was favorably influenced and the use of the drug was probably the determining factor between life and death.

3. In the treatment of hematogenous osteomyelitis sulfone chemotherapy is not a substitute for surgical judgment, operative technique, or meticulous after-care.

Fig 4 This plate represents a case in which the pericardium was not removed. As the opaque mass was being injected it could be seen to pass along the intercostal arteries of both sides thence to the graft, pericardium, and some into the circumflex branch, *A*, of the left coronary artery

lateral. The former received its nourishment through the internal mammary artery and the latter through the intercostal artery. Having prepared the graft, the pericardium was opened, the epicardium and parietal pericardium roughened with a rasp, and the graft sutured with plain No 00 catgut to the heart. The pericardial sack was left open. The chest wall was then closed over artificially inflated lungs.

The animal was again operated upon at 4 and 8 week intervals when branches of the right and left coronary arteries, respectively, were partially obliterated by silver clips.

Approximately 4 weeks after this interference with coronary circulation, the animal was sacrificed and the specimen was injected with a radio-opaque substance. We endeavored to isolate the heart in such a manner that

Fig 5 The photomicrograph shows the fibrosis between the graft and the myocardium. *A*, skeletal muscle, *B*, area fibrosis, *C*, myocardium

the injection mass could not enter the coronary circulation except by way of the graft (Figs 3 and 4).

Bismuth oxychloride and acacia were injected into the cannulas as illustrated in Figure 2.

Graft of omentum to the heart To illustrate this type of procedure the protocol of Dog 10 follows. The anesthesia used was the same as on previous experiments. The omentum was brought into the chest cavity through an opening in the left side of the diaphragm and sutured to the heart as were the muscle grafts. This operation was performed on September 20, 1939. On September 27, 1939, a silver clip was placed on the descending ramus of the left coronary artery. At frequent intervals electrocardiograms were made, as illustrated in Figure 6.

September 25, 1939. Normal sinus rhythm, rate 125. Prominent *Q* wave in all leads and in leads II and III the *S*-wave are even more prominent. *S* *T*₁ and *S*-*T*₂ are practically iso electric. *S*-*T*₂ tends to slope downward, *T*₁ is flat, *T*₂ and *T*₃ are diphasic, *P*-*R*, 0.11, *QRS*, 0.07.

October 16, 1939. Ventricular tachycardia frequently interrupted by auricular and *A*-*V* nodal beats. The rate varies constantly but averages 220. In leads II and III the *QRS* complexes are slightly widened, somewhat bizarre in shape and notched at the peak. There is no demonstrable *S*-*T* segment as the downstroke of the sharply inverted *T*-wave is practically a continuation of the descending limb of the *R* complex. *QRS* equals 0.10.

October 27, 1939. Leads I and II only. Marked sinus arrhythmia, rate 65. *P*₁ iso-electric. *P*₂ con-

Fig. Injection of barium oxychloride and acrylic.

Several special conditions were noted in the postmortem examination of the dogs used in these studies. When muscle was grafted to the heart the graft became quite stiff and the heart action was not free although this apparently did not inconvenience the animal. Omental grafts remained soft and pliable leaving the heart to act more normally.

Microscopic studies of blocks of tissue removed showed some degeneration of skeletal muscle and in all cases an avascular fibrous layer between graft and myocardium (Fig. 5).

Opaque masses entered the coronary tree on several occasions only when the pericardium was not removed. The material reached the coronary arteries through the normally present but enlarged anastomoses between the pericardophrenic branches of the internal mammary artery and the coronary arteries and through small anterior branches of the thoracic aorta which gave off branches to the lateral and posterior surface of the parietal pericardium. These small anterior branches also anastomose freely with bronchial phrenic intercostal and internal mammary arteries.

Fig. 5 This plate represents case 1a, with the pericardium as removed. The graft is fairly vascular but some of the opaque material entered the coronary vessels. 1. Intercoastal muscle graft. B. heart.

Anastomosis of left internal mammary artery to coronary artery. Our first experiments were two attempts to anastomose directly the left internal mammary artery to the descending ramus of the left coronary artery. Both of these procedures failed. The photomicrograph (Fig. 1) shows the close proximity of the two vessels but there is no communication between them. The walls are practically touching each other with only a small strip of exudate between. The coronary artery 4 is patent. The internal mammary artery B contains a recent thrombus. With the use of heparin and an improved technique this type of anastomosis might be possible.

Suture of intercostal muscle and vessels to the anterior surface of the heart. The anesthesia consisted of intratracheal ether oxygen mixture and artificial respiration. In these experiments two types of grafts were used one with a pedicle medial and the other with the pedicle

sharply inverted T_2 remains upright and notched at the peak T_3 increased in amplitude and sharply peaked $P-R$, 0.10, QRS , 0.06 Characteristic of recent infarct

December 15, 1939 Sinus arrhythmia, rate 95 Q waves again present in all leads S_2 and S_1 less prominent than on previous tracings $S-T_1$ and $S-T_2$ slightly depressed and convex downward $S-T_3$ slightly depressed T_1 has turned upright but is of small amplitude T_2 and T_3 have turned upright $P-R$, 0.11, QRS , 0.06 Indicated marked improvement in coronary circulation Residuals of previous infarction practically disappeared

On December 18, 1939, the animal was anesthetized and bled to exsanguination through the left carotid artery This specimen was examined carefully both before and after it was injected and cleared first India ink and then red cinnabar (in water) were injected into the central stump of the left common carotid artery after the innominate artery, the left subclavian artery and the common iliac arteries were tied off

There were firm adhesions of the omentum and parts of the pericardium to almost the entire ventral aspect of the ventricular portion of the heart There were many blood vascular anastomotic connections between omental, pericardial, and myocardial vessels These anastomoses were most numerous along the area normally supplied with blood along the branch of the left coronary artery and at the left basal region of the right ventricle The anastomoses were large enough that the ink passed through the lumens of them but no evidence could be found that the cinnabar particles passed entirely through the lumens of any of them to reach the myocardial vessels The clip on the left coronary artery was found near the base of the anterior branch of this artery The clip had almost completely occluded this artery

CONCLUSION

Our experiments tend to show

1 The direct anastomosis of internal mammary artery to the coronary might be possible

2 The omental graft lends itself best as a possible source of extracardiac blood supply to the myocardium The graft remains pliable and the heart action is free

3 Muscle grafts become quite firm, interfere with heart action and a layer of fibrosis develops between skeletal and myocardial muscles

4 The heart of the healthy dog withstands diminution of its normal blood supply until it reaches the point of infarction and then recovers as demonstrated by the electrocardiogram

5 Vascular connections between the graft and the heart muscle can be demonstrated in microscopic dissections

Additional experiments are being carried out at the present time further to prove these contentions

The writer wishes to acknowledge the assistance of Dr Chester M Kurtz who interrupted the electrocardiograms, Dr P F Swindle who injected omental graft specimen and Dr Elmer Franseen who gave much time and effort in the early phases of this work

PERICARDIECTOMY FOR CHRONIC CONSTRICTIVE PERICARDITIS

W. H. COLE, M.D. F.A.C.S. R. D. WEBER, M.D. and R. W. KEFTON, M.D.
Chicago, Illinois

THE fibrous tissue deposited in constrictive pericarditis results from a previous infection and produces symptoms as the constriction of the heart increases. The deposition of constrictive tissue may involve the pericardium or epicardium, but usually involves both in such a way that the two layers are adherent. Analysis of a large number of cases, reported in the literature reveals the fact that about 20 per cent of them can be proved to be tuberculous in origin the others are secondary to an infective process, of which the respiratory group, e.g. influenza, is important. It is agreed by most authorities making a study of the disease that rheumatic fever is not a primary factor. The disease has been popularized on the continent by Volhard and Schmieden and in this country by Churchill White Beck, and others. The disease is readily confused with diseases such as congestive heart failure hepatic cirrhosis etc. even by trained cardiologists, as is suggested by the fact that it is being recognized and treated in a relatively small number of clinics. It is the chief purpose of this paper to attempt to point out the manifestations and laboratory procedures which will lead to a minimal amount of error in diagnosis.

CLINICAL MANIFESTATIONS

Perhaps the earliest symptoms complained of are weakness and dyspnea. The dyspnea, however is usually noted only upon exertion not being significant while the patient is resting or lying down. As soon as these symptoms develop ascites and edema of the extremities are noted. Usually the ascites precedes the edema of the extremities by several weeks or months. Loss of weight generally occurs, but may not be appreciated by actual weight fig-

ures because of the development of ascites. Tachycardia particularly upon exertion is fairly constant. Fever is absent. There may be a complaint of mild epigastric distress with anorexia. In the advanced stages of the disease slight anemia and a decrease in blood proteins, with a tendency toward reversal, will be noted.

Upon examination one of the most significant findings will be dilatation of the jugular veins, with or without pulsation. Heart sounds are faint but rarely are murmurs present. A paradoxical pulse (thready in volume during inspiration) is fairly consistent. The blood pressure is low and the pulse pressure diminished. In addition to ascites, fluid is usually encountered in the pleural cavity. It was this feature of the disease which Pick stressed when he originally reported observations on the syndrome. Rarely will Kussmaul's sign be encountered unless adhesive pericarditis is also present. Aortic fibrillation is occasionally encountered. Electrocardiograms usually reveal low voltage inversion or flattening of the T waves in leads one or two or both. In 2 or 3 patients, upon whom blood volume findings were made by Burwell and Blalock the volume was found to be 30 to 45 per cent above normal. Cardiac output, however is lower than average. Circulation time is delayed varying between 30 and 60 seconds—normal, 15 to 20. Venous pressure is consistently high ranging between 13 and 35 centimeters of water—normal is 5 to 10. The liver is enlarged particularly in the advanced cases, and as Harrington and Barnes have noted liver function tests will show definite impairment of function. Upon examination the heart shows no enlargement, and in fact frequently is smaller than normal. There may be slight distortion of the lines of the cardiac shadow in so far as some of the normal curves are straightened (Fig. 2a). About 20

From the Departments of Surgery and Medicine, University of Illinois College of Medicine

Fig 1 Excision of the scar should be started over the left ventricle, and an attempt made to find a plane between the scar and cardiac muscle. All landmarks are usually obliterated, but the coronary vessels are illustrated by dotted lines to reveal their relative location. Injury to the coronary artery is dangerous but may be difficult to avoid, for occasionally it is buried in the scar. Insert A shows the type of incision, B, the area exposed and amount of sternum removed in the cases herein reported.

per cent of the patients with constrictive pericarditis have calcified plaques in the thickened pericardium and will be manifested in the x-ray film. Fluoroscopic examination usually reveals decrease in pulsation, particularly on the right side. This lack of pulsation will be best demonstrated by kymographic roentgenogram (Fig 3a).

DIAGNOSIS

Perhaps the disease most readily confused with constrictive pericarditis is congestive heart failure. Valvular diseases will rarely be difficult to eliminate because of the presence of murmurs, which are absent in constrictive

pericarditis. Although dyspnea is common in congestive heart disease, it is not diminished upon rest and lying down as markedly as it is in constrictive pericarditis. Of more importance also is the fact that ascites develops early in constrictive pericarditis, usually preceding the edema of the extremities, in contrast to its significance in congestive heart failure. Fluid is frequently found in the pleural cavities. The liver is usually enlarged. Of still greater importance in differentiation is the normal or slightly decreased shadow of the heart. With equal symptoms, the cardiac shadow in congestive heart failure will be enormously enlarged, whereas it is of normal

Fig. 2a. Roentgenogram of chest of patient in Case 1, before operation. Not the small heart and straight left border—high as pulsating very little on fluoroscopy.

Fig. 3c. An x-ray picture taken 5 months after operation reveals normal shape—its obliteration of the straight, fixed left border.

size or slightly smaller in constrictive pericarditis. Although distention of the jugular veins, elevation of the venous pressure and delay in circulation time may be encountered in congestive heart failure they are of diagnostic importance in constrictive pericarditis because of their frequency. The almost universal presence of a paradoxical pulse in constrictive pericarditis will be helpful in making the diagnosis. When calcification is present

Fig. 3b. An x-ray picture taken 3 months after operation suggests that the heart has shifted upward but may still be fixed at a point on the left border.

in the pericardium the x-ray examination alone will make the diagnosis.

OPERATIVE CONSIDERATIONS

In 1902 Brauer suggested removal of the ribs and costal cartilages from the area over the heart. This operation was performed for constrictive pericarditis, and although a high incidence in improvement in symptoms was noted in a survey by Smith and Liggett, the operation is definitely inferior to actual removal of the constricting fibrous tissue. We are indebted to Delorme and Rehn for the development of the modern operation with removal of the constricting fibrous tissue.

Incision should be started slightly to the left of the sternum at the level of the second rib and curved toward the sternum and out laterally as the level of the sixth and seventh ribs is approached. Although local anesthesia may be used it is the opinion of most men including the present authors, making a study of the disease that a general anesthetic is preferable. The fourth, fifth and sixth costal cartilages and ribs are resected subperichondrially and subperiosteally. The intercostal muscles are cut away from the sternum care being used not to devitalize any of the tissue because it is of great importance in filling up dead space when the wound is closed. The

Fig 3a Roentgen kymogram of Case 1, before operation. Note that pulsation is diminished on both borders of the cardiac shadow.

Fig 3b A roentgen kymogram 3 months after operation reveals fairly pronounced and seemingly normal pulsation on each cardiac border.

internal mammary artery and vein should be ligated proximally and distally. Although some surgeons (Heuer) do not believe partial resection of the sternum is necessary, most, including the present authors, are in favor of removing the left half to facilitate exposure, particularly in excising the scar over the lateral surface of the right ventricle. The reflection of the left pleura is located and dissected outward along with adjacent tissue to allow exposure of the heart. As soon as the heart is exposed, attempt should be made to identify the descending branch of the left coronary artery and the auriculoventricular groove. Usually, however, all landmarks will be obliterated. Worse than this, as Burwell and Blalock have demonstrated, the descending coronary artery itself, is frequently imbedded in the scar, as it was in one of our cases, and may be injured during excision of the scar. Churchill is of the opinion that the scar should be carefully removed from the region of the auriculoventricular groove, but the authors wish to caution that this procedure must be done with extreme care because of the thinness of the auricular wall at the junction. Most authors, and we agree, do not believe

it is necessary to remove the scar from the auricles, or the great vessels, unless the scar is markedly more pronounced here than elsewhere. The essential features consist of removal of the scar from the ventricles and from the apex. The apex is usually densely adherent to the diaphragmatic surface, and it is exceedingly important that this be freed. The excision of the scar over the ventricles should be started on the left side because of the danger of dilatation of the right ventricle if excision is started on the right side. Areas of calcification should be removed only if this can be done safely. Occasionally, the calcified plaque will extend deep into the ventricular wall. Removal might leave such a thin layer of muscle that perforation would develop.

Manipulation of the heart tends to produce arrhythmia. It is exceedingly important, therefore, that if the rhythm of the heart becomes disturbed, all operative manipulation should be terminated until normal rhythm is regained, restitution to a normal rhythm rarely requires more than a minute or two. During the process of excision of the scar a flap of fibrous tissue should be left attached to the heart so that it might be inserted firmly

against any bleeding point whether it be perforation of the ventricle or incision through the descending branch of the left coronary artery. The importance of this precaution was appreciated in Case 1 reported herein when a sudden, severe hemorrhage developed during excision of the scar over the left ventricle. Removal of the scar should be as complete as possible but should not be extended laterally beyond the limits of good exposure because of danger of hemorrhage which could not be controlled with inadequate exposure. If the pleural cavity on either side is entered, the hole should be obliterated immediately and a suture taken to close it. Rarely will this jeopardize the patient's condition to any significant degree.

The dead space created by excision of the ribs is sealed up as well as possible with the pectoral and intercostal muscles. A small rubber drain should always be left in the inferior or superior part of the wound to prevent accumulation of fluid.

One of the most important considerations in postoperative care is oxygen therapy which may be administered by a tent, mask, or nasal tube. Elevation of the back rest of the bed will add to the comfort of the patient. Intravenous fluids should be given with caution because of the severe, sudden strain thrown on the heart incident to the operative procedure. The authors are of the opinion however that a small transfusion in addition to 500 to 700 cubic centimeters of glucose given

slowly is safe and even advisable. Fluids and food are administered as tolerated. Digitalis may be used in the presence of fibrillation but we do not favor its administration for tachycardia alone.

CASE. H. P. No. 62,791, but laborer 5 years of age, was admitted to the Illinois Research and Educational Hospital, August 29, 1938, complaining of abdominal swelling and extreme upon exertion. Eighteen months before admission he had an acute ailment with fever, generalized chills, pharyngitis, and albuminuria followed in few weeks by epigastric distress and generalized edema. Progressive weakness was major complaint. Abdominal paracentesis as performed several times during the last few months before admission to this hospital. At the time of admission to this hospital, abdominal distention—ascites—was sufficient to cause discomfort, but there was no orthopnea.

The temperature as normal, the pulse small and 85 to 95 per minute. The blood pressure as 6 systolic and 90 diastolic. The cervical veins are visible. The lungs are resonant and free from rales. The pericardial impulse as within the mid-clavicular line and there was slight retraction of the heart during systole. The rhythm as regular. The liver was firm and not tender. It extended about 5 centimeters below the costal margin. The spleen was not palpable. The routine urinalysis, blood counts, and serology showed normal findings. The serum proteins were albumin 3.0, globulin 3.45 grams per cent. Fluoroscopic examination demonstrated restricted motion of the heart except at the apex. The meter chest film showed small heart, the right and left borders being straight, thus giving the edge shape. A roentgen-lymogram confirmed the fluoroscopic findings. The venous pressure as 15 centimeters, the decubital circulation time 35 seconds, and the ether time 6 seconds. Abdominal paracentesis yielded 6.5 liters of straw-colored fluid which contained 4.37 grams per cent of total protein. Bacteriological examination—including guinea pig inoculation—was negative. The Mantoux test on 1 cubic centimeter of old tuberculin 1:100,000 gave a strongly positive reaction. The central necrosis. The electrocardiogram showed low QRS, the first lead and inverted T waves in the three standard leads. The T₄ was low. A diagnosis of constrictive pericarditis was made.

Pericardial resection was performed October 3, 1938. The pericardium was adherent everywhere to the heart, but adhesions over the auricles were filmy and readily broken. No landmarks were visible because of the dense scar. The pericardium as attached to the diaphragm. In dissecting through this scar was opened into a cystic cavity containing about an ounce of brownish fluid (thick fibrous material). The pericardium as so adherent to the heart muscle that it could be removed only by sharp

Fig 4b Case 3, no operation, few small cavities containing turbid fluid yielding tubercle bacilli on smear found within pericardial sac at autopsy.

dissection. During the process of cleaning the left ventricle a severe hemorrhage was encountered. A flap of fibrous tissue was rapidly inserted against this point, and two sutures were applied. This controlled the hemorrhage. We removed the scar as far laterally on each side as was deemed safe and freed the apex from the diaphragm. The wound was then closed, interrupted catgut was used and a drain was inserted at one point. The postoperative course was without complications except for a moderate rise in temperature— 101 to 103°F —and the development of a left pleural effusion. Thoracentesis 7 days after operation yielded 1200 cubic centimeters of fluid which contained a few polymorphonuclears, but no organisms were recovered. Later a thoracentesis was repeated. Abdominal paracentesis was never necessary after the operation. Roentgen-kymogram taken 2 months after the operation showed good movement of the ventricular borders. Chest films taken at intervals during the year following operation demonstrated a gradual development of a normal curvature of the ventricular borders and an increase in the heart size toward normal. Symptomatic improvement continued for at least a year after operation. This was demonstrated both in increased exercise tolerance and in a gradual drop in the venous pressure. Table I gives the values for venous pressure, circulation time, and vital capacity. An electrocardiogram taken $1\frac{1}{2}$ years after operation showed better amplitude, but T₂ and T₃ still were deeply inverted. When last seen 2 years after operation he was working full time, and claimed that normal strength and physical reserve had returned.

CASE 2. E. G., No 70,765, of Dutch descent, age 53 years, was admitted to Illinois Research Hospital, on February 29, 1940. His symptoms

were first noted in September, 1936, at which time he complained of dyspnea on exertion. Soon he was unable to walk more than a block without marked fatigue and dyspnea, this was followed by edema of the ankles, but ascites did not develop until 2 months later. With bed rest the ankle edema subsided, but the ascites did not, he remained an invalid henceforth, being unable to be out of bed except for short intervals. Abdominal paracentesis was performed on several occasions by outside physicians before entry to the Illinois Research Hospital. His past history was not significant. He had not had rheumatic fever, nor any known tuberculous lesion.

On examination it was noted that there was no fever, the pulse was 90 and its volume became small with inspiration—paradoxical pulse. There was no dyspnea at bed rest but slight exertion caused marked dyspnea. There were cyanosis and a slight icteric tint. The abdomen was protuberant. The blood pressure was 104 systolic, 72 diastolic, when supine, standing it was 104 systolic and 84 diastolic. There were very prominent, distended, pulsating cervical veins. The veins over the lateral thorax and arms were also distended and prominent. Except for flaring of the costal margins and elevation of the diaphragm the lungs were normal. Cardiac dullness was found 20 centimeters to the right of the parasternal line and to the midclavicular line on the left. The apex beat could not be made out. The tones were normal but slightly decreased in intensity, there were no murmurs. Ascites was present, the liver was palpable three finger breadths below the costal margin, and it was firm and not tender. The spleen was not palpable. Moderate ankle edema was present. There was no clubbing of the nails.

The urine was normal, the blood contained 15 grams per cent hemoglobin, red blood cells, 4,400,000, hit blood cells 700. Wassermann and Kahn tests gave negative reactions. The serum albumin as 3.67, the globulin 4.69, the icterus index. The venous pressure at the antecubital vein was more than 30 centimeters. The decubolus circulating time was 30 seconds and the ether time 3 seconds. The vital capacity was 600 cubic centimeters. After removal of .8 liter of ascitic fluid the vital capacity was 2600 cubic centimeters. The tuberculin test—0.1 c.cm. of old tuberculin, 0.0001—gave an area of redness and slight induration 4 centimeters across. The electrocardiogram showed the QRS waves to be low and slurred and the T waves low and diphasic in the standard leads. The QRS 4 as slurred, T4 low and diphasic. The meter chest film showed normal heart size, a straight right heart border, an unusual configuration of the left, and evidences of pleural fibrosis. Fluoroscopy showed limited movement. Roentgen-lymography showed decreased movement of the right ventricle, good movement in the upper portion of the left ventricle, but restricted movement at the apex.

Pericardial resection was done on March 7, 1930. Exposure of the heart revealed all landmarks gone. The auricles were enormously distended. The ventricles were squeezed down to masses not much larger than lemon by the dense scar tissue. The excision of the thickened pericardium was started over an area which appeared to be the left ventricle. Further dissection of scar tissue was carried to the lateral border on each side. The cardiac muscle was so cyanotic and appeared so friable that we were much discouraged as to the outcome. Neither did the heart bulge out through the opening in the scar tissue as much as we expected. The wound was closed with silk, without drainage. Accumulation of fluid the following day made it necessary for us to insert drain between some sutures.

Patient was sent to the ward and given oxygen therapy. Condition remained unchanged for several days, but 14 weeks after operation, he developed increased signs of cardiac decompensation and died 3 days later with exacerbation of his symptoms.

CASE 3. B. W. N. 68 years, male aged 64 years, was admitted to the Illinois Research and Educational Hospital, September 7, 1930. He had been comparatively well until May, 1929, when he noticed fatigue and weakness, associated with cough, which was occasionally productive of tenacious yellow sputum. Anorexia became marked and he rapidly lost 45 pounds in weight. In June he developed dyspnea, ascites, and edema of the legs. With increasing ascites he developed pain in the upper abdomen. The blood pressure was 140 systolic and 90 diastolic, the pulse 90, and the temperature normal. There was pleural effusion on the right and crepitant rales at the left base posteriorly. The heart borders were found thin normal limits. There were no murmurs. Moderate ascites was present. A mass believed to be the liver extended to

the umbilicus, it was firm and tender. Pitting edema was present at the ankles. Roentgen examination of the chest after thoracentesis showed evidences of pulmonary congestion and some fluid in the right pleural space. The transverse thoracic diameter as 30.6 centimeters and the largest transverse cardiac diameter was 13.3 centimeters. The specific gravity of the pleural fluid was 1.020, the protein content .46 grams per cent. Smears were negative. The culture of the pleural fluid was negative, guinea pig inoculation was negative. The tuberculin test using 0.1 c.cm. of 1:1000 old tuberculin intracutaneously was positive. The venous pressure taken on October 2, 1930 gave a value of 30 centimeters. Decubolus circulation time was 34 seconds, the ether time as 4.6 seconds. Urinalysis showed trace of albumin and occasional pus cell. The hemoglobin was 16.5 grams per cent, the red blood cells, 5,300,000, white blood cells, 6,750. The Wassermann and Kahn tests were negative. The serum albumin as 3.6 per cent and the globulin 8 per cent. The icterus index normal. The electrocardiogram showed low QRS complexes and low diphasic T waves in the standard leads.

Because of the patient's age, the pulmonary congestion, and failure of fluoroscopic examination to reveal restriction of cardiac movements, diagnosis of cardiac decompensation due to myocardial insufficiency secondary to arteriosclerosis as accepted in preference to constrictive pericarditis.

Decompensation progressed. Repeated thoracentesis and abdominal paracentesis were necessary in the course of the disease. Painful mass developed in the right lower quadrant. Death occurred on February 19, 1930.

Autopsy showed firm cartilaginous pericarditis reaching thickness of millimeters and inseparably fused to the epicardium. The scarred pericardium contained several small collections of milky fluid. Smears of this fluid showed numerous acid fast organisms which on culture were found to be tubercle bacilli. The outer surface of the pericardium was smooth. The coronary arteries were patent throughout but contained an occasional thrombotic deposit. There was also tuberculous peritonitis with the omentum formed into thick mass across the upper abdomen. The mass in the right lower quadrant was composed of several adherent loops of bowel. There was milky tuberculous of the liver, kidney, spleen, adrenals, retroperitoneal nodes, and lungs. From the autopsy findings it was evident that the tuberculous pericarditis was of much longer duration than the tuberculous peritonitis.

IMPORTANT POINTS IN DIAGNOSIS AND TREATMENT

Beck has stressed the physiologic concept that the heart in constrictive pericarditis is a heart under compression. It is a small one

imprisoned by the constricting adhesions. Its embarrassment is caused by an inability to hold in diastole sufficient blood to maintain an adequate arterial circulation. Hence the cardiac output (Heuer and Stewart) of necessity falls and under exertion the heart rate increases as a compensatory adjustment. When the output falls excessively, there is a discrepancy between the blood volume and the vascular bed. The vasomotor center becomes unable to reduce the arterial bed correspondingly and the blood pressure falls. The circulation is inadequate and it can be readily appreciated that these patients will first complain of indefinite symptoms, as easy fatigability, slight dyspnea after exertion, and later, more and more serious limitation of activity. When they are examined at this stage the heart borders are normal both on physical and fluoroscopic examination. Usually no murmurs are heard, and the circulatory inadequacy is attributed to myocardial weakness with a loss of cardiac reserve. The patient is considered to have a decompensation which produces symptoms but, as yet, no signs.

As the condition progresses and the compression becomes more severe, the blood piles up in the vena cava, and gradually backs into the finer systemic venous radicles. The venous pressure in the vena cava which normally is negative, becomes positive, and continues to rise until it exceeds the limiting pressure exerted on the relaxing auricle. When it is in excess of the intrapericardial pressure the blood flows in to fill the auricles. The height of the venous pressure gives one an index of the severity of the cardiac compression. The antecubital venous pressures in the 3 cases were, respectively, 26, 30, and 30 cubic centimeters of salt solution. With the increasing venous pressure the blood accumulates in the first available reservoir. All the systemic veins have valves and these combined with the pumping effects of muscular action tend to keep the blood flowing towards the heart. The hepatic veins are without valves and the liver is readily distensible so it first receives the extra blood. The liver then becomes congested, large, tender, and establishes a portal decompensation. With long continued con-

gestion liver damage occurs, producing varying pathological pictures, ranging from fatty livers through fibrosis to cirrhosis. It is interesting that the spleen is not usually palpable. When the patient is seen at this stage of the disease he presents a normal sized heart without murmurs, prominent veins, ascites, and a large liver. After paracentesis, the spleen is still not palpable. A plate of the chest shows no evidence of pulmonary congestion. The abdominal findings are so striking that the distention of the veins, unless marked, is overlooked. Even if the patient complains of dyspnea this also is easily attributed to a lowering of the vital capacity by upward pressure from the distended abdomen. Hence the ascites now stands out as the prominent symptom demanding explanation. If the patient is middle aged, the diagnosis of cirrhosis becomes probable. The liver function tests, however, do not indicate as much damage as would be expected in a frank cirrhosis. The spleen also is not palpable. Hence, carcinomatosis with fluid formation and tuberculous peritonitis will be considered. The ascitic fluid will have a lower protein content than would be expected in these conditions and the clinical course will have been too protracted to render the diagnosis of carcinomatosis tenable. A tuberculous peritonitis is eliminated with much more difficulty. In fact, it existed in Case 3 along with a tuberculous pericarditis. At this point the patient is re-examined carefully. The prominent veins are again noted, a venous pressure reading is taken. This is increased and rises still higher when pressure is exerted over the liver. The correct diagnosis is now possible, and should be made.

As the condition progresses there is added to the picture a generalized edema beginning in the feet extending later to the arms, face, and body. This represents a more advanced stage of venous stasis. The blood volume will be increased. The circulation time will be prolonged. Since these findings are present in all cases of congestive heart failure, the significance of an increased venous pressure is lost. The diagnosis still should be made at this stage. Cardiac decompensation does exist. The point at issue is the cause of the decompensation. If the patient had a rheu-

matic valvulitis or arteriosclerotic heart disease with myocardial damage, one would expect to find a heart somewhat larger than normal and a lung which shows passive congestion. This passive congestion would be revealed by transitory attacks of blood tinged expectoration and by an x ray plate revealing pulmonary congestion. In constrictive pericarditis the blood does not get into the heart and the quantity which does get into the aorta is readily pumped into the arterial circulation. There is therefore, no opportunity for blood to accumulate in the lung. On the other hand a clear lung is not compatible with a diagnosis of congestive heart failure, left ventricular failure or a rheumatic valvulitis.

When a pleural effusion appears the diagnosis becomes increasingly difficult. One now has the complete picture of congestive failure. The pleural effusion is still to be attributed to systemic venous congestion of the parietal pleura. However it encroaches on the lung to such an extent that evidences of pulmonary congestion appear secondarily. The history of the appearance of ascites prior to the frank decompensation and the findings of a small heart without murmurs should point to the proper diagnosis. A cardiac cirrhosis also can be eliminated by the absence of a mitral stenosis.

If the compression of the heart is produced by a combination of constrictive adhesions and fluid, then the heart size will be increased. This will add to the diagnostic difficulties, but it will not make them insuperable.

In 1 of the cases herein reported the constrictive pericarditis was definitely secondary to tuberculosis. In the 2 others, both of which were operated upon, a strongly positive tuberculin test was obtained. However microscopical examination of the scar tissue revealed no evidence of tuberculosis.

Of the 3 patients operated upon 1 died. He survived the operation, but showed only mild improvement, and died several weeks later with symptoms typical of cardiac failure. Unfortunately autopsy was not obtained. This patient was 53 years old and had had severe symptoms for about 4 years. In going over the patients reported in the literature

the poor results, particularly as related to mortality were much more common in elderly patients. In fact, very few who were operated upon were as old as this patient. It seems obvious that considerable irreparable myocardial damage existed in this patient. As a matter of fact, the heart muscle as uncovered by excision of the scar was so cyanotic and friable that we considered it almost necrotic and feared spontaneous perforation. Heart muscle which was as unhealthy as this obviously could not regain much of its original function. We are, therefore strongly of the opinion that the mortality rate will be much lower in young people whose cardiac muscle is more apt to be reasonably well preserved. It is even possible that patients past the age of 50 should be operated upon only if they appear to be reasonably good operative risks.

Observations on vital capacity might be important in determining prognosis as far as fatality following operation is concerned. For example, the vital capacity of patient in Case 2 who died several weeks after operation was 1600 before abdominal paracentesis, and 1600 after paracentesis contrasted to a vital capacity of 4600 in Case 1 in which recovery following operation was satisfactory.

The authors wish to emphasize particularly that recovery may take place for at least a year following operation. For example, in Case 1 patient showed improvement for at least a year following the date of operation. In fact, at the end of 1 year his strength had not completely returned to normal although he was relatively free from symptoms. When last seen, which was almost exactly 2 years after operation, he stated that his strength had entirely returned, that he was free from symptoms, and working daily running a press.

SUMMARY

Undoubtedly innumerable cases of constrictive pericarditis are erroneously diagnosed as congestive heart failure, hepatic cirrhosis, etc., because of the similarity of symptoms to those of constrictive pericarditis. It is particularly important that this error be avoided because sufficient operative reports are now available to establish the fact that although

the mortality rate is high, the results otherwise are excellent. Perhaps the first symptom of constrictive pericarditis is weakness, followed soon by dyspnea upon exertion. Of great diagnostic significance is the fact that in this disease the dyspnea is not present while the patient is inactive and that ascites precedes edema of the extremities. Distended neck veins, high venous pressure, paradoxical pulse, and small cardiac shadow constitute important evidence for the diagnosis.

Since conservative treatment of the disease is hopeless, operation should be performed early, before myocardial damage due to compression, etc., is irreparable. Results are much better in young people, very few patients in late adult life survive the operation. Results may not be immediate, as emphasized by the fact that in one of our patients strength was still subnormal 1 year following operation, but 2 years after operation he felt perfectly normal and was working daily running a press.

EXTENSIVE CUTANEOUS BURNS

With Special Reference to the Blood Chemical Changes

ROBERT MAYO TENERY, M.D. New York, New York

THE historical background of burns has been adequately covered in many previous publications and need not be repeated. However one quotation from the older literature seems pertinent:

From the very great variety of applications so strongly recommended by the first characters, a biased individual would be at a loss on what to determine. I presume one of the great causes of error is the assigning of various applications the cure of slight burns, some of which doubt could have got well without any and perhaps much sooner than with those which were used. This mistake frequently happens from good motives, and by the best intentioned people for if we have seen a person recover from any complaint during the use of any particular means, we naturally imagine such beneficial effect to have arisen from that cause although upon further investigation, it may be found to have been inadequate.

Thus, in 1797 Edward Kentish expressed his opinion of the contemporary investigation and treatment of burns. In the past 50 years many different local applications have been recommended likewise many theories have been presented to explain the cause of the systemic manifestations seen in burned patients.

No attempt has been made in this study to evaluate the various local applications. The feeling in this clinic has been that cleanliness is the most important factor in the local care of the burned area. The patients to be presented in this study were given adequate doses of morphine on admission then, when comfortable and if the general condition permitted, the burned areas were washed with gauze sponges, soap and water while débridement was carried out at the same time. Most burns except those of the face and hands were covered with either a tannic acid silver nitrate (3) eschar or a gentian violet silver nitrate (5) eschar. Blair jelly was applied to

burns of the face and hands immediately after cleaning and after 48 hours, continuous saline soaks were applied.

Underhill and his associates (27) have shown that immediately after severe burns primary shock may develop as the result of pain and fright. They also stressed the importance of hemoconcentration resulting from plasma loss into the burned area, mainly during the first 24 hours (22, 23, 24, 26, 27). Aldrich has emphasized the rôle that absorption of bacterial toxins from an infected burned area may play in producing systemic changes. The time relationship between these three factors may be diagrammatically represented as shown in Figure 1. With adequate therapy these factors may be prevented or controlled but even so the burned patient may still develop a syndrome characterized by lowered blood pressure, tachycardia, hyperpyrexia, anorexia, malaise, increasing lassitude, and later in severe cases, delirium, coma, and death. This condition which usually makes its appearance 24 to 72 hours after the burn is usually referred to as the toxemia of burns, or more preferable—the toxic stage of burns. The etiology of this syndrome has been the subject of much study and discussion and the recent trend of interest in this respect has been in the field of blood electrolytes.

Underhill in 1923 (24) pointed out a decrease in serum chlorides following severe burns. In 1926 Davidson (7) confirmed this and made a note of a chloride retention which he concluded must lie in the tissues. One year later Davidson (8) reported a study of serum proteins in which he found a slight decrease over a period of days after the burn, though frequently an increase was noted in the presence of hemoconcentration. Wiener, Rowlette, and Elman, in 1936 emphasized the fact that large amounts of parenteral saline solution frequently carries the serum protein to an

From the Department of Surgery, Wayne University College of Medicine, Detroit, Michigan.

edema level. All of these findings have since been confirmed by several groups of investigators (9, 14, 25), however, very few studies have been made on the effect of severe burns on potassium. Wilson (32) found a consistent, marked decrease in the serum sodium level corresponding with the general condition of the patient, treatment with desoxycorticosterone acetate tended to elevate the serum sodium with a coincident clinical improvement in the patient. Wilson also noted elevations of the serum potassium. Scudder (19) has presented a study of plasma potassium in 6 cases of severe burn in which he found elevations similar to those he had found in other forms of shock, he employed eschatin¹ in the treatment of these cases. Keeley, Gibson, and Pijoan carried out blood electrolyte studies on 7 dogs after experimental burning but found no increase in the serum potassium. This finding may possibly be explained on the fact that the potassium in the dog's red cells is very nearly the same as in the serum, thus, less potassium would be liberated after cell damage and intravascular hemolysis.

If one considers the known pathological physiology which follows severe burns, an elevation of plasma potassium would be predicted for several reasons: (a) the tissue autolysis, which follows death of cells after burning, necessarily sets free the intracellular potassium, (b) hemolysis of the red cells within the vessels of the burned area likewise liberates potassium, (c) in the presence of a low-

Fig 1 Showing the chronological relationship between primary shock, hemoconcentration, and systemic manifestations of infection (Modified from Gunn and Hillsman)

ered blood pressure renal excretion is diminished, thus hindering the elimination of excess potassium, (d) the renal damage which occasionally follows severe burns would have a similar effect, (e) liver damage frequently occurs, and this may interfere with the hepatic storage of excess potassium, and finally, (f) adrenal degeneration, infarction, and hemorrhage have all been described as occasional findings at autopsy, and in such cases sodium and potassium metabolism would certainly be effected.

It is the purpose of this study to evaluate the rôle of blood electrolyte changes, especially potassium, in the production of the symptoms of the toxic stage of burns.

METHOD OF STUDY

Eight cases of severe burn entering the Detroit Receiving Hospital were selected for study. There were 2 females and 6 males in this group, and the ages ranged from 8 to 51 years. The causes of injury were house fire, clothing on fire, and gas explosion. The

depth of burn in each case was diagnosed as first, second, third, and fourth degree burns (Dupuytren's classification, 15) the smallest total area involved was 15 per cent and the largest 50 per cent of the total surface area of the body (Berkow scale)

Blood pressure studies could not be carried out on any of these cases as all of them were burned over both upper extremities. Evi-

dence that the toxic stage was present is based purely upon clinical judgment with the aid of the temperature and pulse charts. L. T. and O. C. showed no definite toxic symptoms. M. P. B. L. and W. P. showed moderate reactions but at no time were in shock. These 5 patients recovered. Unquestionable severe symptoms of the toxic stage were present from the second 24 hour period after burning until

Table III—L T white, ♀ aged 5 5 per cent of body burned Clothes on fire.

Table IV — B L, white, ♂, aged 11 years, 20 per cent of body burned. Clothes on fire

death in Cases F B, G B, and C R. At autopsy F B showed an extensive bronchopneumonia, probably as the result of inhaling hot fumes, however toxic symptoms were present for at least 3 days before the pneumonia developed. In Cases G B and C R no definite pathological cause of death could be found at autopsy. Table I shows the post-mortem findings in these 3 fatal cases.

Parenteral plasma, whole blood, glucose, and saline were given each patient as indicated. It is granted on retrospect that the treatment was not ideal in all cases, but it was sufficient to prevent primary shock, to control hemocoagulation, and to keep infection to a minimum.

All blood samples were taken at an interval when no parenteral fluid was being administered. Ten cubic-centimeters of venous blood were drawn into a clean syringe and carefully transferred to a tube containing 2 milligrams of dry purified heparin. The tube was then tipped four or five times in such manner that the heparin dissolved without causing foaming of the blood. Two cubic centimeters of blood were then immediately poured into another tube for hematocrit and whole blood potassium determinations, and the remainder of the blood was centrifuged without delay.

This extreme care and speed is necessary because of the great error in potassium determinations which can result from diffusion of potassium from cells to plasma or by liberation of cellular potassium through hemolysis. Heparinized plasma was chosen in preference to serum because a greater interface exists between clot and serum than between centrifuged cells and plasma—thus allowing a greater area for diffusion. No blood was taken

after death in Cases F B G B and C R. be cause of the immediate postmortem rise in potassium which Scudder (20) has demonstrated.

The hematocrit was determined by centrifuging for 20 minutes at 2,000 revolutions per minute in Van Allen hematocrit tubes (28) and the micro-Kjeldahl method (16) was used for the estimation of plasma protein. Potassium was determined on plasma and whole blood by the photo-electric chloroplatinic

acid method of Tenery and Anderson. Cell potassium was calculated by the formula

$$\text{Cell potassium} = \left(\frac{\text{whole blood K} - \text{plasma K} \times \frac{100}{\text{hematocrit}}}{\frac{100}{\text{hematocrit}}} \right) \times \frac{100}{\text{hematocrit}}$$

The method of Hoffman and Osgood was used for plasma sodium and plasma chlorides were determined by the method of Wilson and Ball (30)

Table VIII —C R, white, ♂, aged 35, 40 per cent of body burned

Table IX —G.B, white, ♂, aged 26, 50 per cent of body burned House fire

We have found an average normal range for each of these determinations to be hematocrit, 40 to 45 per cent cells, plasma potassium, 14 to 18 milligrams per 100 cubic centimeters whole blood potassium, 150 to 200 milligram per 100 cubic centimeters—depends on hema

tocrit cell potassium, probably 375 to 425 milligrams per 100 cubic centimeters plasma sodium 140 to 150 milli-equivalents per liter plasma chloride, 98 to 110 milli-equivalents per liter plasma protein 6.5 to 7.5 grams per 100 cubic centimeters.

FINDINGS

The results of these various procedures on the 8 patients studied are presented in Tables II to IX. The time relationships between the temperature, pulse, parenteral fluid, and blood chemical determinations are shown the small arrows at the top of each temperature chart indicate the time at which each blood sample was taken. Hematocrit is expressed as per cent of cells, potassium as milligrams per 100 cubic centimeters and sodium and chlo-

ride as milli-equivalents per liter. Figures 2, 3 and 4 are composite graphs of the cases studied.

In all of these patients the hematocrit rose (Fig. 2) but only in C.R., G.B. and F.B. did it reach a very high level before adequate therapy brought about dilution. It was of great interest to note the relatively high readings of the first sample from each case though taken only a short time after burning. F.B. had a hematocrit of 53 per cent only 1 hour after receiving burns of 25 per cent of the body. In a patient, whose case is not reported in this series who had burns over 100 per cent of the body surface we found a reading of 71 per cent in venous blood 1 hour after burning; this would indicate that about one half of the total plasma volume had been lost

Fig. 3—Composite graph of erythrocyte plasma cell percentage on the 8 patients studied.

Fig. 4—Composite graph of plasma sodium and chloride on the 8 patients studied.

in that short time. In general, we have found that about one half of the hemoconcentration that is to occur was present 6 hours after the

burn. This indicates the need for plasma transfusion as early as possible as hemoconcentration is easier to prevent than relieve.

The plasma protein levels (Fig. 2) in these cases are similar to those previously reported. G. B. was given large amounts of saline and relatively little plasma in the first 54 hours after injury with a resultant marked drop in plasma protein accompanied by clinical edema. M. P. was given no parenteral saline and consequently had only a gradual slight lowering of the protein. The findings in all cases indicate the need for conservatism in the use of parenteral saline, and show a definite advantage in the use of plasma for preventing and relieving hemoconcentration.

Plasma potassium findings were rather disappointing (Fig. 3). Increases in the potassium level did occur in the first 48 hours in all patients except L. T. whose burns were the slightest; however in no case did the potassium reach a toxic level. It is quite probable that elevations would have been greater had the patients not received treatment, but the important point is that the toxic symptoms of burns were present without the presence of a toxic plasma potassium level.

Since the potassium content of cells is about twenty times greater than that of plasma, whole blood potassium varies almost directly with hematocrit changes and so means very little in itself.

The cell potassium is of interest though somewhat confusing (Fig. 3). The normal variation of potassium in the cells is rather inconstant; however in general a decrease occurred in most of the cases during the first 48 hours which was followed by a rise. Estimations of the cell hemoglobin content indicate that part of this decrease is the result of intracellular dilution; this may be further confirmation of the concept that the red cells become swollen in shock (6).

In spite of the relatively large amounts of parenteral saline the plasma chlorides consistently decreased slowly though in no case did this reach a dangerous level (Fig. 4). In contrast, the sodium level fell to a much greater degree. In M. C., F. B. and G. B. the plasma sodium dropped below 130 milliequivalents per liter. This could be a manifestation of adrenal insufficiency in spite of the normal plasma potassium because it has been shown that symptoms of Addison's dis-

ease can exist with a normal potassium if the sodium is low. G. B. was given eschatin; this was followed by a rise in the plasma sodium and chloride, but clinically the patient remained in circulatory failure and died.

C. R. showed a definite picture of burn toxemia without lowered plasma sodium and the remaining cases in general showed no relationship between the plasma sodium level and the presence of toxic symptoms. That sodium may play a large rôle in the morbidity of burned patients cannot be denied, and further investigation is definitely indicated.

Plasma vitamin C determinations were carried out on F. B. Unfortunately the first sample was not taken until 45 hours after burning; at this time the level was 0.04 milligrams per 100 cubic centimeters. He was then given large doses of ascorbic acid by mouth, and 3 days later the level was 0.14. This man was an old alcoholic and so may well have had a vitamin deficiency before his accident; however it is interesting to speculate as to whether or not his injury had anything to do with his having such a very low level of vitamin C.

CONCLUSIONS

1. Primary shock, hemoconcentration and infection may all occur after extensive burns. With adequate therapy these can be controlled, but some patients will still show signs of the toxic stage of burns.

2. The data presented here indicate that under the usual mode of therapy (intravenous plasma and saline) the toxic symptoms may develop and cause death without marked changes in the blood electrolyte pattern. The exception to this may be sodium which is definitely lowered; however these data indicate no definite relationship between this drop and the clinical picture.

3. We do not imply that blood electrolyte changes are of no importance following burns; such changes must be carefully watched and controlled, otherwise the morbidity and mortality will be markedly increased.

4. Plasma is the ideal parenteral fluid to combat hemoconcentration and should be started within the first 6 hours after the burn is received.

The plasma protein levels (Fig. 2) in these cases are similar to those previously reported. G B was given large amounts of saline and relatively little plasma in the first 54 hours after injury with a resultant marked drop in plasma protein accompanied by clinical edema. M I was given no parenteral saline and consequently had only a gradual slight lowering of the protein. The findings in all cases indicate the need for conservatism in the use of parenteral saline, and show a definite advantage in the use of plasma for preventing and relieving hemoconcentration.

Plasma potassium findings were rather disappointing (Fig 3). Increases in the potassium level did occur in the first 48 hours in all patients except L T whose burns were the slightest however in no case did the potassium reach a toxic level. It is quite probable that elevations would have been greater had the patients not received treatment, but the important point is that the toxic symptoms of burns were present without the presence of a toxic plasma potassium level.

Since the potassium content of cells is about twenty times greater than that of plasma, whole blood potassium varies almost directly with hematocrit changes and so means very little in itself.

The cell potassium is of interest though somewhat confusing (Fig 3). The normal variation of potassium in the cells is rather inconstant however in general a decrease occurred in most of the cases during the first 48 hours which was followed by a rise. Estimations of the cell hemoglobin content indicate that part of this decrease is the result of intracellular dilution this may be further confirmation of the concept that the red cells become swollen in shock (6).

In spite of the relatively large amounts of parenteral saline the plasma chlorides consistently decreased slowly though in no case did this reach a dangerous level (Fig 4). In contrast, the sodium level fell to a much greater degree. In M C F B and G B the plasma sodium dropped below 130 milliequivalents per liter. This could be a manifestation of adrenal insufficiency in spite of the normal plasma potassium because it has been shown that symptoms of Addison's dis-

ease can exist with a normal potassium if the sodium is low. G B was given eschatin this was followed by a rise in the plasma sodium and chloride but clinically the patient remained in circulatory failure and died.

C R showed a definite picture of burn toxemia without lowered plasma sodium, and the remaining cases in general showed no relationship between the plasma sodium level and the presence of toxic symptoms. That sodium may play a large rôle in the morbidity of burned patients cannot be denied, and further investigation is definitely indicated.

Plasma vitamin C determinations were carried out on F B. Unfortunately the first sample was not taken until 45 hours after burning at this time the level was 0.04 milligrams per 100 cubic centimeters. He was then given large doses of ascorbic acid by mouth, and 3 days later the level was 0.14. This man was an old alcoholic and so may well have had a vitamin deficiency before his accident however it is interesting to speculate as to whether or not his injury had anything to do with his having such a very low level of vitamin C.

CONCLUSIONS

- 1 Primary shock, hemoconcentration, and infection may all occur after extensive burns. With adequate therapy these can be controlled but some patients will still show signs of the toxic stage of burns.

- 2 The data presented here indicate that under the usual mode of therapy (intravenous plasma and saline) the toxic symptoms may develop and cause death without marked changes in the blood electrolyte pattern. The exception to this may be sodium which is definitely lowered however these data indicate no definite relationship between this drop and the clinical picture.

- 3 We do not imply that blood electrolyte changes are of no importance following burns, such changes must be carefully watched and controlled, otherwise the morbidity and mortality will be markedly increased.

- 4 Plasma is the ideal parenteral fluid to combat hemoconcentration and should be started within the first 6 hours after the burn is received.

TENERY EXTENSIVE CUTANEOUS BURNS, BLOOD CHEMICAL CHANGES

5 Parenteral saline is essential after severe burns as a method to combat the tendency for plasma sodium and chloride to fall and perhaps to prevent elevation of plasma potassium, however, saline must be given judiciously because large amounts bring about a marked decrease of plasma protein, often to the edema level

6 The value of adrenal cortical hormone cannot be evaluated from our small experience with these preparations

7 The etiology of the toxic stage of burns is still unknown, the observations here presented indicate that blood electrolyte changes are not the answer Perhaps a toxin is produced in the burned area Wilson (31) has demonstrated the presence of a toxin which he believes is formed gradually by the autolysis of the injured tissue, and Rosenthal (17, 18) has found a histaminoid substance in burned tissue which is neutralized by serum from recovered cases of burn—neither of these concepts has been disproved

I wish to thank Dr Charles G Johnston and Dr J Logan Irvin for their aid and advice in this investigation I also wish to thank Dr O A Brines for his aid in the pathological interpretation of the autopsy material presented

POSTOPERATIVE INFECTION

Measures of Control

GEZA d TAKATS, M.D. F.A.C.S. and JOSEPH H. JESSER, M.D. Chicago, Illinois

THE possible sources of contamination of the surgical field are many. Cole and Elman listed them as follows: (1) mouth and throat of the operating room personnel (2) skin of the surgeons and assistants' hands (3) patient's skin (4) faulty sterilization in autoclave (5) suture material chiefly catgut (6) gross break in aseptic technique (7) trauma to tissues, poor hemostasis, sutures under tension. To this one may add the fluctuations of immunity and changes in the virulence of bacteria, which may convert a subclinical unrecognizable contamination into a manifest, clinical infection.

The purpose of this discussion is to describe the methods utilized to minimize the dangers from the sources enumerated and to present statistical data based on the study of clean surgical wounds. All operations were performed at St. Luke's Hospital, Chicago, and some of the suggestions incorporated originated from members of the operating room committee and the surgical supervisors whose help is gratefully acknowledged.

THE ELIMINATION OF SOURCES OF INFECTION

1. Mouth and throat of the operating room personnel. For several years one of us (G. de T.) has been interested in an inexpensive, easily laundered comfortable mask, which would efficiently filter the exhaled air of bacteria. It has been repeatedly shown by Davis, Walker, Waters, Blatt, and many others that the ordinary four to six ply gauze mask is permeable to bacteria and that the adequate surgical mask has not been found. Arnold, using the air centrifuge of Wells, has shown that when a person gargled with a 1:100 dilution of a culture of *Bacillus prodigiosus* and then talked into the Wells machine for 10 to

12 minutes, with his mouth and nose masked with the customary gauze mask, 1,362 bacteria of the same kind were recovered per 10 cubic feet of air. He also showed that the permeability of the mask increased with time. In the first 2 minutes only 20 bacteria passed through, but the count increased with every 2 minute period and during the fifth 2 minutes 317 bacteria passed through per 10 cubic feet of air. Obviously the ordinary six ply gauze mask when worn for an hour or more is incapable of filtering bacteria. In hot weather the masks are often moist when removed and some surgeons even moisten the mask before use for cooling purposes. Such masks seem quite useless and one wonders whether Hertzler's contempt of masking the mouth or nose does not have some justification as far as the gauze mask is concerned. Gauze or calico masks containing rubber cellophane plastic, or any other impermeable material have not solved the problem. We have tried every one of these. It is true that the impermeable material incorporated into a pocket of the mask prevents a direct spray of bacteria into the wound but they simply deflect the bacterial current and the air of the operating room receives an unfiltered stream of bacteria. The air contamination of the operating room has recently received a great deal of emphasis and the 'deflector' type of masks certainly do nothing to minimize this source of contamination.

Obviously the proper mask has to fit the face closely and permit free breathing through its texture. When Professor Arnold of the Department of Bacteriology was approached to study the bacteriological aspects of this problem he had already possessed some observations relating to the relative efficiency of various textiles to absorb bacteria. Silk, linen, and cotton absorbed bacteria poorly. Wood cellulose in the form of a craped wadding, called cellucotton showed remarkable

From the Surgical Service of St. Luke's Hospital and the Department of Surgery, University of Illinois.

absorbing qualities In a series of laboratory experiments, Arnold came to advocate the use of cellucotton as an effective air filter He pointed out that if all the air could be made to pass through the cellucotton mask the bacteria would remain on the cellulose fibers but leakage around the edges of the mask, which occurs with the average surgical mask, especially with that of the hood type, produces contamination of the air

The sterilization of the air in operating rooms, as approached with such vigor and ingenuity by Hart and his associates (13, 14, 15), is only a partial and certainly an indirect solution of the problem As long as it is generally admitted that the degree of air contamination in any room is directly proportional to the duration of occupancy, the number of occupants, the percentage of carriers and the intensity of the air pollution, effective masking seems to be the crux of the situation The elimination of the carriers has been tried in different services (Meleney, Hart) and has been found to be impracticable Cultures from the nose and throat change from day to day The training of student nurses is seriously hampered by their frequent and repeated elimination from the operating room, internes and attending men in a busy general hospital cannot be made to stop their work if their throat cultures become positive At St Luke's Hospital the attempt was made for a short period to eliminate all student and graduate nurses from the operating room and the maternity wards whose throat cultures were positive for hemolytic streptococci, the *Staphylococcus aureus* carriers were not included in this group Table 1 shows the result of throat cultures on a total of 99 student and graduate nurses over a 10-week period It is obvious from this greatly abbreviated report that in the fall of 1936, 20 per cent of the nursing staff connected with operating rooms or maternity wards carried hemolytic streptococci After a short period of elimination of the carriers the nursing school properly pointed out that as long as the attending and interne staff were not cultured the prophylactic value of such a measure was dubious, furthermore, the training of the student nurses was seriously hampered

TABLE I —THROAT CULTURES OF THE NURSING STAFF

October 21, 1936—February 9, 1937

	Cases
Negative on first culture	79
Positive on first culture	20
Negative on second culture	7
Positive on second culture	6
Not recultured	7

Of the 6 positives on second culture 3 remained persistently positive 2 became intermittently negative, 1 remained persistently negative Of the negatives on first culture 3 became intermittently positive Cultures were taken once a week

In a personal communication Dr Frank Meleney stated that during the late winter and early spring months the incidence of positive throat cultures in the personnel amounted to a peak of 35 per cent, they still maintained (February 15, 1937) an elimination of the carriers for the Sloane Hospital as it was felt that on the maternity service the nurses come into much closer contact with the patients, particularly in the postpartum period

For over a year the cellucotton masks as suggested by the work of Arnold have been in use Eight layers of cellucotton were placed in a pocket of a large gauze mask, a flexible metal band was inserted into the upper part of the mask, which bent to fit the nose of any individual (Walker) and which prevented steaming of the glasses There were two objections to this mask First, it required considerable time to place the cellucotton in the pockets Second, breathing through the gauze mask with the 8 ply cellucotton was not easy Some surgeons refused to wear the mask A few nurses complained of a stuffy odor when the mask was worn for a long time as in the maternity wards

We then tried a commercial mask, which had an excellent cut to fit any type of face and which contained, as a filter, a variety of compressed cotton The bacteriological work on the efficacy of this material has been reported by McKhann and his associates It seems not inferior to cellucotton Finally the operating room committee adopted a homemade flannel mask which has now been in steady use for almost 2 years Its use has been adopted by the Canadian Red Cross for Canadian medical services At present it is in general use at our hospital The mask is made of a 9 by 6 inch

When Professor Arnold of the Department of Bacteriology was approached to study the bacteriological aspects of this problem he had already possessed some observations relating to the relative efficiency of various textiles to absorb bacteria. Silk, linen and cotton absorbed bacteria poorly. Wood cellulose in the form of a crimped wadding called *cellucotton* showed remarkable

From the Surgical Services of St. Luke's Hospital and the Department of Surgery, University of Illinois.

absorbing qualities In a series of laboratory experiments, Arnold came to advocate the use of cellucotton as an effective air filter He pointed out that if all the air could be made to pass through the cellucotton mask the bacteria would remain on the cellulose fibers but leakage around the edges of the mask, which occurs with the average surgical mask, especially with that of the hood type, produces contamination of the air

The sterilization of the air in operating rooms, as approached with such vigor and ingenuity by Hart and his associates (13, 14, 15), is only a partial and certainly an indirect solution of the problem As long as it is generally admitted that the degree of air contamination in any room is directly proportional to the duration of occupancy, the number of occupants, the percentage of carriers and the intensity of the air pollution, effective masking seems to be the crux of the situation The elimination of the carriers has been tried in different services (Meleney, Hart) and has been found to be impracticable Cultures from the nose and throat change from day to day The training of student nurses is seriously hampered by their frequent and repeated elimination from the operating room, internes and attending men in a busy general hospital cannot be made to stop their work if their throat cultures become positive At St Luke's Hospital the attempt was made for a short period to eliminate all student and graduate nurses from the operating room and the maternity wards whose throat cultures were positive for hemolytic streptococci, the *Staphylococcus aureus* carriers were not included in this group Table 1 shows the result of throat cultures on a total of 99 student and graduate nurses over a 10-week period It is obvious from this greatly abbreviated report that in the fall of 1936, 20 per cent of the nursing staff connected with operating rooms or maternity wards carried hemolytic streptococci After a short period of elimination of the carriers the nursing school properly pointed out that as long as the attending and interne staff were not cultured the prophylactic value of such a measure was dubious, furthermore, the training of the student nurses was seriously hampered

TABLE I — THROAT CULTURES OF THE NURSING STAFF

October 21, 1936—February 9, 1937

	Cases
Negative on first culture	79
Positive on first culture	20
Negative on second culture	7
Positive on second culture	6
Not recultured	7

Of the 6 positives on second culture 3 remained persistently positive
2 became intermittently negative 1 remained persistently negative
Of the negatives on first culture 3 became intermittently positive Cul-
tures were taken once a week.

In a personal communication Dr Frank Meleney stated that during the late winter and early spring months the incidence of positive throat cultures in the personnel amounted to a peak of 35 per cent, they still maintained (February 15, 1937) an elimination of the carriers for the Sloane Hospital as it was felt that on the maternity service the nurses come into much closer contact with the patients, particularly in the postpartum period

For over a year the cellucotton masks as suggested by the work of Arnold have been in use Eight layers of cellucotton were placed in a pocket of a large gauze mask, a flexible metal band was inserted into the upper part of the mask, which bent to fit the nose of any individual (Walker) and which prevented steaming of the glasses There were two objections to this mask First, it required considerable time to place the cellucotton in the pockets Second, breathing through the gauze mask with the 8 ply cellucotton was not easy Some surgeons refused to wear the mask A few nurses complained of a stuffy odor when the mask was worn for a long time as in the maternity wards

We then tried a commercial mask, which had an excellent cut to fit any type of face and which contained, as a filter, a variety of compressed cotton The bacteriological work on the efficacy of this material has been reported by McKhann and his associates It seems not inferior to cellucotton Finally the operating room committee adopted a homemade flannel mask which has now been in steady use for almost 2 years Its use has been adopted by the Canadian Red Cross for Canadian medical services At present it is in general use at our hospital The mask is made of a 9 by 6 inch

piece of outing flannel bought on the market for 9 cents a yard.¹ It is inserted between two layers of a 44 by 40 thread mesh gauze. There is one thickness of this gauze on each side. An ordinary one half inch tape 44 inches long is sewn along the upper and lower border of the mask. Two 1 inch tucks are taken at the two sides of the mask, shortening their lengths to 4 inches and insuring a close fit over the cheeks. A pocket is left for the insertion of a flexible metal band for closer fit on the nose. The cost of the mask to the hospital, including material and labor is 5 cents. It can be re-sterilized many times.

2. *The skin of the surgeon and assistants hands.* The most revealing work on this subject has been that of Price. He recommended a soap and warm water scrub of the hands and forearms for 7 minutes, which rids the skin of gross dirt, fat transient bacteria, and approximately 50 per cent of the basic flora; this is followed by a 3 minute friction (by the clock) with 70 per cent (by weight) ethyl alcohol, which reduces the flora to less than 2 per cent. Ethyl alcohol, 70 per cent must be prepared by weight and not, as usually done by volume ethyl alcohol has a very narrow range of effective germicidal concentration. At 25 degrees Centigrade the following formula will give a solution approximately 70 per cent by weight 95 per cent alcohol, 815 cubic centimeters, plus cold distilled water to make 1000 cubic centimeters 60 per cent by weight approximately 70 per cent by volume is almost worthless (23). Price pointed out that 1 minute contact with 70 per cent alcohol is equivalent to 4 3 minutes of scrubbing and also suggested a mixture of alcohols which is even more effective but which we have as yet not tried. Curiously enough the 7 minute scrub followed by 3 minutes immersion with friction (gauze or wash cloth) has been our method of skin preparation for many years.

Beneath the dry rubber glove the bacterial flora doubles in 40 minutes; hence glove punctures are dangerous. Devenish and Miles

emphasized the leakage of *Staphylococcus aureus* through glove punctures occurring during operation; such punctures occurred in 24 per cent of all cases and could be reduced to only 14 per cent in spite of eliminating patched gloves. They felt that the real danger of contamination with *Staphylococcus aureus* comes not from the nose and throat but from the skin of carriers leaking through the glove punctures or through the sleeves of linen gowns, moistened by sweat. Skin carriers could be best detected by culturing the sweat within the glove at the end of the operation. At our hospital one surgeon whose incidence of postoperative infection was unusually high was found to be such a carrier. According to Devenish and Miles a course of ultraviolet radiation had no effect on the skin of one of their carriers.¹

3. *The skin of the patient.* Some of our surgeons have closely followed the routine advocated by Koch. Briefly his method is as follows: (1) careful soap and water cleansing with plain white soap of the field of operation on the afternoon preceding the operation. Protection of the cleansed field with a sterile dressing bladder or towel. (2) A second soap and water cleansing just before operation, for 10 minutes. The soapy solution is rinsed away with sterile water and the sterile draping is applied. No antiseptics are used.

We have followed this procedure for operations on the extremities or orthopedic work. For the majority of patients, however our choice is still an iodine-alcohol preparation. With the exception of an occasional case of iodine sensitivity of which the patient is usually aware we have not experienced the much discussed iodine dermatitis. It is essential, however to apply the 5 per cent tincture of iodine once, carefully to remove the excess with alcohol and then to apply a third dry swab the remaining iodine and alcohol being wiped off. The edges of the prepared field which are covered by sterile towels, are carefully wiped off. Trickling of the tincture of iodine into genitorectal areas or to the back of the patient is avoided. We have returned to the iodine-alcohol preparation after a thorough

¹The types of Caesin formal which serve as effective bacterial filters have been given to us by Dr. C. J. McKeown at Cambridge, Edwards 27-34 and Edwards 27-25. We gratefully acknowledge Dr. McKeown's help. Study of these swabs at home contained. Of results obtained by Dr. McKeown of our resident staff, the one in present use proved to be most efficient.

²Many believe that some backbone of mercury on hands that will tolerate it, following alcohol, is an added safeguard.

trial of the mercuric-chloride-acetone-alcohol mixture of Arnold, of mercurochrome, mer cresin and metaphen. While in a large general hospital, such as ours, every surgeon has his own favorite method, a gradual return to iodine is noticeable. A 2 per cent iodine solution in 70 per cent (by weight) of alcohol has been advocated by Price. It is inexpensive and has an important quality which test tube experiments for antiseptic coefficients will never demonstrate, i.e., it produces a reactive hyperemia of the skin, which we have demonstrated with measurements of skin temperature, this together with a local leucocytosis is an excellent adjunct to primary union. For certain regions of the body, such as the genital, anal, and axillary regions, a 3 per cent aqueous solution of iodine has been employed with lack of iodine dermatitis, provided the field is carefully wiped off with a dry sponge.

The fingering of the prepared skin with the gloved hand to outline the line of incision is inconsistent with the customary efforts to cover the incised skin with towels and isolate the wound with towel clips. If preliminary marking of the line of incision is desired, we advocate the use of a two per cent solution of brilliant green applied before the iodine-alcohol preparation. Mercurochrome and metaphen solutions efface the brilliant green mark.

4 *Faulty sterilization in autoclaves* This subject was reviewed by Dandy in 1932. He advocated sterilization in an autoclave for one hour with a constant pressure of not less than 20 pounds. Meleney stated that sterilization for 30 to 45 minutes and prolonging the evacuation time at minus 10 to 15 minutes was sufficient to kill organisms and spores. With less time and pressure the center of the central drum may remain contaminated. At St. Luke's Hospital, 18 pounds of pressure are used for 1 hour followed by another hour of vacuum. A temperature of 250 degrees F is obtained.

5 *Suture material* The whole subject of catgut versus silk (11, 12, 17, 25, 31) and the recent work of Meade and Ochsner with cotton cannot be entered here. We simply wish to present our own procedure, learned in the schools of Kocher and developed in this country by Halsted. We use silk, and as fine

a silk as possible, unless some definite contraindication exists. The silk is usually interrupted, the peritoneum is closed with a continuous catgut suture and catgut is used in entero-anastomoses for the suture of the mucosa. Infection is not a contraindication to silk, and we have repeatedly tied large vessels with heavy silk or even tape in the presence of infection. We believe that the steady use of catgut increases the incidence of infections not only because the sterilization of catgut is not as simple but mainly because catgut produces local areas of exudation, and collections of serum predispose to infection. It must be admitted, however, that if catgut were used in such fine varieties as silk is, the difference between the true materials might not be so striking (17). If cotton continues to be as successful as the first reports indicate (21), we may look for a further improvement in suture material. It has been tried on our service in over 100 major operations.

6 *Gross break in aseptic technique* In large hospitals with student nurses and internes rotating every 6 weeks in the operating room, with a large surgical staff whose training is not always of identical nature, a break in asepsis has to be continuously guarded against. Visitors should always wear sterile caps, gowns, and have their mouths and noses covered. Visitors in nonsterile gowns when they lean against the drapings or the exposed backs and elbows of the surgical team are a definite menace. The dripping of perspiration from the foreheads of the surgeons and assistants is a frequent source of danger. We have tried some of the sponge-mops which are on the market, but their wear is cumbersome and may increase perspiration. While air conditioned operating rooms eliminate much of the perspiration, large blocks of ice placed in front of a fan have been tried, their use may be objected to as they stir up dust in the operating room and facilitate the migration of bacteria toward the wound.

A frequent source of a sudden spray of dust and bacteria is the sudden shifting of the lighting system directly over the field of operation. When such a shift becomes necessary it is wise to cover the field with a sheet during this maneuver.

7 Trauma to tissues poor hemostasis sutures under tension. One hardly needs to be labor the point that rough handling of tissues, insufficient hemostasis, sutures under tension which invite localized areas of ischemia, favor the multiplication of ever present bacteria. It is less often realized that foci elsewhere in the body may be stirred up by the trauma of the operation and anesthesia and bacteria may then localize in the surgical field. This is particularly true of acute respiratory infections. During an influenza epidemic in a large base hospital, one of us observed the suppuration of many clean wounds that had been healing without reaction for 5 to 7 days. When the epidemic hit the clean surgical ward a large percentage of the wounds became infected with bacteria which are secondary invaders following the virus, namely the *Streptococcus hemolyticus*, and the *Staphylococcus hemolyticus*. A patient, then, should never be operated on except in emergencies when a respiratory infection is present not only because of the danger of postoperative pulmonary complications but because of the possible localization of bacteria in the surgical field. The classic experiment of producing a localized abscess at the site of trauma following an intravenous injection of bacterial suspension is sufficiently known, but its application to the localizing effect of surgical trauma is often ignored.

8 Other sources of infection. Another source of infection in postoperative wounds is the presence of bacteria in a latent "resting" state in the tissues. This problem in its relation to the activation of phlebitis in varicose veins has been discussed elsewhere (8). The principle of activating resting infection by surgical trauma and especially by creating anaerobic or partially anaerobic conditions has an important application in all surgical operations where potentially infected fields are invaded. Gas gangrene following amputations for vascular disease is an example (9). The torn or overstretched muscle of a muscle splitting incision may be of more harm to the patient than a clean, sharp cut in the muscle, provided it does not damage its nerve supply.

That more infection does not result from such endogenous sources is no doubt due to the patient's immunity. This immunity may

be local developing around a chronic anal fistula, or general. But the immunity of patients to specific bacteria varies from day to day. Schafer found that in the months of January and February immunity of animals is at its ebb for diphtheria. Epidemics of scarlet fever are explainable not by the sudden appearance or multiplication of bacteria but by a sudden decrease of immunity. The sudden overwhelming septicemia following clean operations, which, according to Hunt, occurs in 1 of 2000 to 3000 cases may be explained in the absence of any recognizable source of infection by such a sudden loss of immunity.

Mrs. D. T. A 4 year old rather obese woman had a small epigastric hernia which was repaired under local anesthesia. An all-silk technique was used. The operation lasted 36 minutes. On the night of the operation the patient had a severe chill, 4 hours she died of fulminating septicemia. Hemolytic streptococci were cultured from the blood, the spleen, and other organs. The field of the operation showed no infection. All possible sources of infection were checked. Throat cultures of the operating room personnel were negative. The procaine solution was sterile. The silk, as usual, was sterilized with instruments in boiling water for 15 min. The patient's throat was slightly infected unfortunately. Culture was made from it.

Such a case, which may occur in the practice of any surgeon, illustrates the difficulty of detecting some sources of infection or preventing their occurrence.

MATERIAL STUDIED

The purpose of our present study was to see what results were obtained with the methods here outlined, to emphasize the weak points, and if possible, suggest their remedy. The material to be presented illustrates the results obtained in a general hospital in which yearly over 7,000 major operations are performed. As some of the special sheets were incompletely filled out, we can present data on only 606 clean operations. An infection sheet was attached during the year of 1938 to the hospital record of every major surgical case. The classification of postoperative infections is that of Claude Beck as reported by William C. Beck in his recent survey on morbidity caused by operative complications (Table 11). For a check on our operating room technique we could utilize only the first

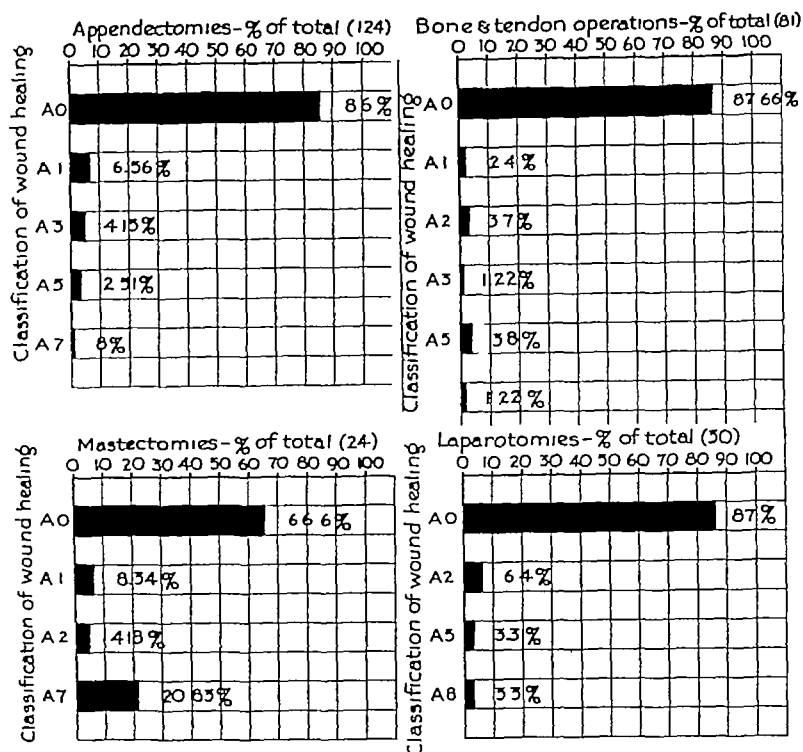

Chart 3 Wound healing classification

tomies and orthopedic operations, the lowest percentages were encountered following hysterectomies and mastectomies. Reddened skin edges were encountered in 20.3 per cent following hysterectomies and only in 2.4 per cent after orthopedic operations. Stitch abscesses, A₂, were seen most often after laparotomies and least frequently after herniotomies. Slight serous or purulent discharge was seen most frequently after appendectomies, indicating the necessity of careful protection of the abdominal wall from contamination and the occasional use of drainage or delayed closure as advocated by Collier and Volk. Hematomas were most frequent after thyroidectomies, which, of course, is due to the nature of the operation. We have commented on the large percentage of skin necrosis following mastectomies.

EVALUATION OF RESULTS

The difficulties in evaluating the results of such a survey are obvious. In a general

hospital, the technique of different services and of individual surgeons varies. There were, of course, certain nonvariables, such as (1) the sterilization of instruments, suture material and surgical linen, and (2) the new air-filtering masks, which we do believe have an important rôle in diminishing air borne infection. The incidence of stitch abscesses, slight and serious wound infections, infected hematomas and septicemia totals 3.81 per cent of all clean operations, a truly excellent record compared with other carefully conducted surveys (22). On the basis of some experience with trying to establish the incidence of surgical infections from the ordinary hospital records, we have to come to the conclusion that aside from being a cumbersome and lengthy task, many minor infections are unrecorded and perhaps never known to anyone but the interne removing the stitches. We believe that in order to get comparative results, similar record sheets would have to be used by all institutions really interested in their per-

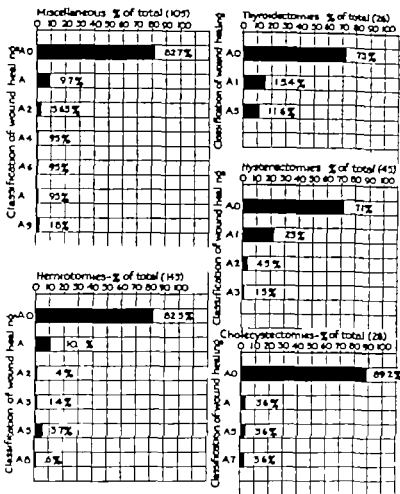

Chart Wound healing classification.

of the record by the resident on gynecology, or to the difficulty of sterilizing the field is uncertain. This service has since cut down the percentage to a small minimum. Cholecystectomies show a very high percentage of primary wound healing—89.2 percentage. In this hospital drainage is used in all cases for 2 to 4 days. In a miscellaneous group including neurosurgical cases, vascular surgery plastic surgery, thoracic and genito-urinary patients, wound healing compared favorably with most other groups, owing perhaps to the special preoperative care of these patients.

Appendectomies did equally well with the exception of minor skin infections (Chart 3). The statistics on bone and tendon operations

are favorable especially in regard to the low incidence of minor skin infections and of hematoma. Following mastectomies, necrosis of the skin edges seemed to be a complication too often encountered. This is obviously due to the effort of removing as much skin as possible or saving too much undermined skin and may point to a more frequent use of immediate or delayed skin grafts. Other laparotomies behaved much like the average group.

When the operative procedures are grouped according to the postoperative reaction, the points mentioned obtain renewed emphasis (Chart 4). Primary union, A₀, showed the highest percentage following cholecystec-

mum of infection following clean cases. We will have to pay more attention to the sterilization of the skin and to glove punctures. We are not in a position to evaluate the bactericidal effect of radiant energy on the contamination of the air in the operating room, but it is our feeling that the use of effective air filters in closely fitting masks is another step in the same direction, certainly a simpler one. Perhaps the mouth and pharynx of the operating room personnel could be temporarily sterilized with tablets or trochees, but there is no good evidence yet that this is practicable.

The fluctuations of immunity and their relation to sudden overwhelming infection is another open question, only slight use has been made in this hospital of the prophylactic doses of sulfanilamide before operations that readily lead to contamination from within the body, such as intestinal resections.

Whether the contamination with *Staphylococcus aureus* comes from the nose and throat of the personnel in the operating room (13, 14) or whether it is skin contamination (10) is impossible to decide. In an excellent review of the problem of air contamination, Walters and Magath lean toward the view that air contamination through respiratory passages and its effective sterilization by radiant energy is far from being proved. Certain it is that expensive and complicated ultraviolet radiation in operating rooms is still in the experimental stage and need not as yet burden the budget of the average general hospital.

SUMMARY

1. The sources of contamination of the surgical field have been discussed. The use of a new flannel mask has been described which efficiently filters bacteria but does not deflect them. The sterilization of the skin of the patient with soap and water, followed by iodine and 70 per cent alcohol, is advocated. Measures have been suggested which seal the suture line following operation. Silk was preferred to catgut.

2. Following the classification of Claude Beck, 606 clean operations have been studied in regard to their postoperative wound reaction. Postoperative infection resulting in prolonged stay in the hospital or danger to

life occurred in 1.59 per cent. A total of 3.81 per cent of all clean operations showed wound infection. Special interest has been focused on reddened skin edges as evidence of inadequate sterilization of the skin. Hematoma and marginal necrosis occurred more frequently in certain types of operations. The material was studied according to operative procedures and plotted against the different grades and types of delayed union.

3. The study is intended to stimulate similar efforts of record keeping in other hospitals. As a result of our own survey, further improvement in our records has already taken place. The filling out of the record is simple, not time consuming, and should be entrusted to the resident.

centage of disturbed or delayed wound healing. The survey of William C. Beck offers a standardization of such studies.

The reddened skin edges are undoubtedly due to inadequate sterilization of the skin or a postoperative contamination of the wound. The gynecological service, on which 1 per cent mercurochrome was used, had the highest incidence. The highest and lowest percentages were 20.3 per cent and 2.4 per cent. In addition to the soap and water iodine and alcohol preparation we advocate two other measures to prevent delayed contamination of the skin after it has been sutured. One is the use of silverfol under which we have never seen a true cutaneous infection; the other is the gluing of the gauze dressing to the skin with mastisol¹ which one of us (G. de T.) has been using since 1915 and which makes excellent small dressings for aseptic wounds. The importance of late skin infections is best seen in the many ambulatory vein ligations. In the hot summer months, where perspiration can readily increase the incidence of bacteria around the suture line, reddened skin

edges are far more frequently encountered. In over a thousand ambulatory vein ligations, which are not included here, mastisol was used but no silver foil or antiseptic dusting powder has been employed. During the hot spell of July, 1940, we became convinced, however, that ambulatory patients, especially require added care for the protection of the suture line from cutaneous bacteria. The pubic area is especially prone to minor skin infection, which may explain the high incidence after hysterectomies and inguinal hernias.

The results obtained here are readily surpassed by the individual surgeon who is especially conscious of postoperative infections. In surveying the practice of other hospitals one surgeon stated that "postoperative infection has occurred so infrequently that we have almost stopped thinking about it. This may be true of some surgeons of our institution. We were really interested, however, in determining the chances that the average patient has of developing an infection when operated on at St. Luke's Hospital. We have used rigid criteria for the establishment of the data published here.

It seems as if there is an irreducible mini-

¹One mastisol 40 grams, bromal, oil 200 grams. Filter then add guttae 25 of castor oil.

mum of infection following clean cases. We will have to pay more attention to the sterilization of the skin and to glove punctures. We are not in a position to evaluate the bactericidal effect of radiant energy on the contamination of the air in the operating room, but it is our feeling that the use of effective air filters in closely fitting masks is another step in the same direction, certainly a simpler one. Perhaps the mouth and pharynx of the operating room personnel could be temporarily sterilized with tablets or trochees, but there is no good evidence yet that this is practicable.

The fluctuations of immunity and their relation to sudden overwhelming infection is another open question, only slight use has been made in this hospital of the prophylactic doses of sulfanilamide before operations that readily lead to contamination from within the body, such as intestinal resections.

Whether the contamination with *Staphylococcus aureus* comes from the nose and throat of the personnel in the operating room (13, 14) or whether it is skin contamination (10) is impossible to decide. note that the pregnancy occurred in a patient in whom there was a veritable toboggan slide from the fallopian tube to the ovary. Just as fertilization of the ovum in the tube is a preliminary stage in the everyday occurrence and development of normal intra-uterine gestation, likewise it should be possible for the impregnated ovum to slide downward into the gaping recently ruptured ovary, there to develop. Whether an endometrial implant must furnish a favorable site for nidation of the ovum as was possible in this patient with endometriosis, is an additional problem, mention of which may suffice here.

Nearly 60 cases of primary or 'true' ovarian pregnancy have been recorded in the literature of this number only approximately 60 are authentic instances of primary ovarian gestation. Despite the fact that only a small number of cases are recorded in the literature and many of these can-

not be accepted as authentic primary ovarian pregnancy is probably not at all rare and it very likely explains a considerable proportion of the cases of serious hemorrhage from the ovary also, it doubtless accounts for some instances of secondary abdominal pregnancy—a much more common affection than has heretofore been realized. (Lull has had 5 cases of abdominal pregnancy in his own practice.)

CONCLUSION

1. A case of living unruptured primary ovarian pregnancy has been described.

2. Evidence has been submitted in substantiation of the thesis that primary ovarian pregnancy may occur after fertilization in the fallopian tube just as normal intra-uterine gestation develops after fertilization in the fallopian tube. The belief that primary ovarian pregnancy occurs solely after fertilization of the ovum before its escape from the ovary, is unwarranted.

3. Despite the fact that only a small number of cases of primary ovarian pregnancy are recorded in the literature and a considerable proportion of these are not authentic, it would appear that ovarian pregnancy often escapes recognition and it is always to be considered in cases of ovarian hemorrhage which are serious enough to require surgical intervention.

THE DISRUPTION OF ABDOMINAL WOUNDS

A Continuation of a Previous Report

FRANK GLENN, M D, F A C S, and S W MOORE, M D
New York, New York

OVER 3 years ago we reported 22 cases of disruption of abdominal wounds (1) occurring in a series of 2,927 patients on the surgical service of the New York Hospital during a period of 3 years and 8 months. Since the mortality of this serious complication continues to be from 22 to 50 per cent in various reported series we have again reviewed our experience with an additional 3,490 cases and consider in this study, therefore, a total of 6,417 abdominal wounds. From the data collected in the study of the first series of 2,927 patients certain conclusions were drawn leading to the application of general policies in the second series of 3,490 patients treated over a similar period of time. The value of such a study is suggested by the results since in the first series the incidence of evisceration was 0.75 per cent and in the second series 0.60 per cent. More significant perhaps is the difference in mortality rate as that in the first series was 45.45 per cent while in the second series it was 19.04 per cent, a mortality rate of 30.2 per cent for the total of 43 eviscerations.

In the continuation of the comprehensive study of this problem of wound disruption on the surgical service of the New York Hospital, the records of all patients upon whom abdominal operations were performed between September 1, 1932, and January 1, 1940, were reviewed with respect to the following factors: location of the incision, suture material used in closing, the operation performed, the lesion, whether malignant or nonmalignant, and whether infection was present previous to operation or presumably introduced during the operative procedure. Our total of 6,417 abdominal wounds were followed by 43 eviscerations, an incidence of 0.66 per cent. The general information concerning the series is presented in Table I.

In Table II the influence upon the incidence of evisceration of the site of incision and the type of suture material employed, together with an evaluation of the incidence of wound evisceration for the entire period, are presented.

From the Department of Surgery, of the New York Hospital and Cornell University Medical College

Table III approaches the subject from a different viewpoint. Here the figures are given for incidence of evisceration in various operations and again reference is made to the suture material employed.

Table IV summarizes the distribution of suture material employed. It is to be observed that catgut has been used with increasing frequency and we feel that an interpretation of this point is worthy of discussion. The indications for the use of silk have been more rigidly adhered to from year to year. *Catgut has, therefore, had to bear the brunt of all cases of infection or possible infection. The incidence of wound evisceration, however, has been almost equal in the two obviating, therefore, any preference for safety in so far as wound closure is concerned.*

TYPES OF CLOSURE

1 *Catgut closure* a Interrupted catgut closure. The peritoneum is closed with a continuous suture of No. 0 plain or No. 1 20 day chromic catgut. The fascia is approximated by a series of interrupted sutures of chromic catgut. No. 1 Stay sutures of silk worm or "dermo" are placed so that they embrace the fascia only.

b Interrupted catgut closure with figure-of-8 sutures. This is a modification of a, instead of interrupted chromic sutures, the figure-of-8 type of suture with No. 1 20 day chromic is employed.

c Interrupted catgut closure with drainage. No. 1 20 day chromic catgut is used to close the peritoneum. Instead of one continuous suture, one continuous suture starts from each extremity of the wound and is brought to the point where the drain emerges. At this point on either side of the drain, a single reinforcing suture of the same material is placed. The single suture is referred to as a "safety suture." The fascia is closed in the manner described and stay sutures complete the closure.

2 *Silk closure* a Silk closure without drainage. A continuous suture of twisted surgical silk No. 7 approximates the peritoneum, and interrupted sutures of the same material unite the fascia. When stay sutures are employed they are of the same silk and form a lateral figure-of-8, in-

TABLE I.—GENERAL INFORMATION

Number of abdominal operations	6,417

Incidence, per cent	66
Deaths	4
Mortality per cent	30

cluding the fascia. The subcutaneous tissues and skin are closed with interrupted silk (No. 5) sutures.

b. Silk closure with drainage. This closure is the same as b in previous list except that silk, No. 7 is used in place of catgut. The safety sutures of silk are employed. Stay sutures may or may not be used; the subcutaneous tissues are not approximated, unless they are unusually thick. Ordinarily the deep skin sutures (No. 5 silk) suffice to bring these tissues into approximation and reaction around the drain is less likely to persist in the surrounding tissues if sutures are omitted.

3. *Silk and catgut closure.* A continuous suture of No. 0 or No. 1 plain catgut or No. 0 or No. 1 chromic catgut is used for the peritoneum. The fascia is approximated by interrupted sutures of twisted surgical silk, No. 7 or figure-of-8 sutures of the same material. Interrupted sutures of silk No. 5 are used to approximate the subcutaneous tissue and skin. Stay sutures, when employed, are buried, consist of double silk, No. 7 and form a vertical figure-of-8 without including muscle.

4. *Silver wire closure.* This is the through-and-through silver wire closure as described by Read, Zinninger and Merrill. A suture of silver wire on an atraumatic needle is introduced from the skin through the subcutaneous tissues and fascia down to and through the peritoneum, and is then returned to the skin, layer by layer. Silver wire sutures of No. 20 round wire should be inserted about 3 centimeters apart and when all have been placed they are drawn taught and each one is secured separately by twisting. No guards to protect the skin from the wires are employed.

In our previous report we warned against the use of silk and catgut in the same wound. The 77 cases reported here of closure of abdominal wounds with silk and catgut show none of the unfavorable complications that we have suggested. The definition of a silk and catgut wound is, however, demanding of explanation. The use of a silk suture, or a catgut suture to the peritoneum with silk ligatures and silk sutures to the fascia, subcutaneous tissue and the skin does not present the same situation as does the use of both catgut and silk material for suture and ligature in the more superficial layers. The use of a long, continuous silk suture to the peritoneum is ob-

jected to by some surgeons because, they contend it produces a permanent distortion of the peritoneum. Furthermore, they object to its use on the ground that if the wound becomes infected a protracted time is required for the expulsion of the continuous silk suture during which period a foreign body sinuses persist.

We have felt an added security in the use of through-and-through silver wire closures and although the incidence of wound disruption in our series of 385 is 1.30 per cent, we believe that this would have been much higher in the same group of cases with any other suture material. The indications previously set up have been the basis for its use. We recommend that silver wire closure be used in the presence of massive abdominal infection, in wounds which have been grossly contaminated by gastrointestinal contents, and in all cases debilitated by malignancy or long standing chronic disease associated with anemia as well as for the secondary closure of disrupted wounds.

Our experience as detailed in Table V continues to be rather unique in the preponderance of disruption in male patients as compared with other reports in the literature. This is most nearly approached by Melony and Howes who report 70 per cent eviscerations occurring in male patients. The total incidence here is approximately 90 per cent male patients who have had wound disruptions.

ANALYSIS OF EVISCERATIONS

No age is immune, evidently, from wound disruption as our youngest patient was 8 months old and the eldest 76 years of age. The majority, however, are to be found in the fifth and sixth decades, or in the age in which malignancy is most likely to occur.

In our previous report we noted that our findings were in agreement with those of many authors in that we reported an incidence of wound disruption of 1.20 per cent in abdominal wounds for malignant disease which was almost twice the incidence of wound disruption in nonmalignant cases. Since that report our experience has been even more striking for in 557 patients with malignant disease there were 10 eviscerations, an incidence of 1.8 per cent. In 1,139 patients with malignant disease there were 16 eviscerations, an incidence of 1.39 per cent, while in the same period 27 eviscerations occurred in 5,278 patients without malignant disease, an incidence of 0.51 per cent, giving us now an incidence of wound disruptions almost 3 times greater in malignant disease than in nonmalignant disease. Paralleling the importance of malignancy from the standpoint of the possibility of wound disruption is the associated high mortality rate, for in the 16 patients having wound disruptions in malignant disease the mortality rate was 56 per cent, whereas in nonmalignant cases the mortality rate was 18.51 per cent.

Fig. 1 Location and designation of incisions employed

Of all the known predisposing factors to wound evisceration, debility has received the greatest emphasis. This term is a comprehensive one and is generally used to denote weight loss, weakness, anemia, and early fatigue on exertion, commonly seen in patients suffering from malignant disease and especially those whose malignant lesion is ulcerated with resultant bleeding and infection. In our first series of eviscerations there were 11 patients labeled as being debilitated prior to operation, while in this series of 21 patients there were 8. The red cell count ranged from 2.5 to 5.9 million and in many instances the recorded pre-operative red blood count was done after numerous transfusion. The significance of avitaminosis has become more important in our experience and for this reason we are at the present time insistent that those vitamins known to be concerned with wound healing, in particular

vitamins B and C, be administered before and after operation parenterally if they cannot be given by mouth

Arteriosclerosis and hypertension, insofar as we have been able to observe, do not play any significant rôle in wound disruption. Diabetes associated with arteriosclerosis and commonly recognized as a factor in lowering resistance to infection has not accounted for a single instance of evisceration in our series. Syphilis, long emphasized in the surgical literature as being responsible for poor healing of wounds, seems to have played no part in our group. Only 2 of these patients were found to have positive Wassermann reactions.

As to their location, the 43 wound disruptions were distributed as follows: Upper right rectus, 26, lower left rectus, 6, upper left rectus, 3, lower right rectus, 3, McBurney, 2, middle right rectus, middle left rectus, and transverse umbilical each one. The upper right rectus incision is by far the one most frequently employed, aside from the McBurney, in operations upon the abdomen. Likewise, it is through this type of incision that operations on the biliary tract have been done. Upper abdominal incisions, it would seem, are more likely to be subjected to greater mechanical strain than those of the lower abdomen. In addition, there is greater likelihood of peritonitis originating in the upper abdomen to spread to the entire peritoneal cavity than when it arises in the lower quadrants where there is a tendency to localize in the pelvis. It is for this reason that gynecological surgery is associated with a low incidence of wound evisceration.

Drains were used in 15 of the 43 patients. It is our general impression that drainage of a wound properly closed does not materially increase the probability of its disruption.

The time of disruption following operation is of significance. Although most disruptions occur between the fifth and tenth day after operation, we have had them occur as early as the first and as late as the thirtieth day. The immediate factors of wound disruption continue to be those associated with upper respiratory infection and abdominal distention. Coughing and vomiting remain the two most common symptoms that appear on the charts of these patients at the time of disruption. It seems unnecessary to stress the importance of combating postoperative pulmonary complications by rebreathing with carbon dioxide, shifting position immediately after operation and doing everything possible to prevent postoperative atelectasis. Persistent vomiting may be controlled by the use of the Wangenstein

method of decompression or Miller Abbott double lumen tube, and we recommend their use for it is believed that this has been of importance in reducing the incidence of wound eversion.

In these 43 patients, secondary closures were accomplished as follows: 33 with silver wire, 7 with packing and adhesive strapping, 1 with silk, 1 with catgut, and 1 with silkwormgut. Packing and adhesive strapping were used on those patients who were considered too ill even to subject to a secondary closure with silver wire. One of those died and 3 later developed incisional hernias. Following the secondary closure the patients remained in the hospital from 1 to 16 days.

The mortality rate for our entire series of 43 cases is 30.2 per cent. In our first report there were 10 deaths occurring in 2 instances of wound disruption or a mortality rate of 45.45 per cent. In our last 2 disruptions there have been 4 deaths, or a mortality rate of 9.4 per cent. The lowered mortality we attribute to early recognition of the eversion and to the prompt secondary closure of the wound before dehiscence has taken place through its entire extent.

POINTS TO EMPHASIZE

During the past 2 years there has appeared in the surgical literature a number of articles favoring the use of silk suture material. Whipple, Jenkins, Shambaugh, Howes, and others have reported their favorable experiences with the use of this suture material. The master of silk surgery" was Halsted and it was chiefly his accurate understanding of wound healing and his execution of a meticulous surgical technique that established its use. It may seem logical to assume that an absorbable suture material which will disappear following the healing of the wound would be preferable to one that remains in the tissues, but in clean wounds the amount of reaction about the silk sutures is minimal. It is our opinion that many of the advantages of silk

suture material are based upon the meticulous type of surgery it requires rather than on the strength of the suture material. The terms silk surgeon and catgut surgeon have come to have a definite meaning to the profession. In both groups excellent results have been obtained in the suturing of an abdominal wound. It is therefore important in the consideration of this subject to look upon the problem in a broader sense than the literature indicates at present. We should keep in mind the general status of the patient, his nutrition, whether or not he is anemic, and the disease that has necessitated an operation as well as the structure of the parts involved in the closure of the abdominal wound. The meticulous care exercised by the surgeon in doing an operation should be paralleled by the post-operative care of that individual in order that the anatomical and physiological integrity of the abdominal wall may be re-established in as short a time as possible. When all of these factors are recognized and receive proper attention the incidence of abdominal wound disruption will be further diminished.

FRACTURES OF THE MANDIBLE

M S STROCK, D M D, Boston, Massachusetts

A COMBINATION of reasons has produced greater interest in fractures of the mandible. The number of such fractures has increased since the advent of the automobile. Today thorough roentgenographic examination reveals many fractures that formerly went unrecognized. Recently devised appliances have made available simple and practical methods of treatment which give encouragement to the novice. The general surgeon has begun to recognize that he has not done his best for the patient if he has not restored normal occlusion.

The many recent papers on fractures of the facial bones and their management disclose a striking lack of agreement in this field of surgery. The missionary work of Kazanjian has done much to bring order out of chaos. He has demonstrated the impracticability of expensive appliances which take days to construct. He has emphasized the importance of training the oral surgeon in the use of mechanical devices. He has overthrown old accepted theories by proving them wrong, to wit, direct wiring and absolute fixation. Many of the principles described herein are either his teachings or slight modifications of them.

The threat of war and the mobilization of medical units has brought before us the need for uniformity of treatment. It is obvious that many of the principles developed by Kazanjian¹ in the last war have not become popular. In civilian hospitals, for instance, we still see complete fixation of one jaw against the other, the use of complicated splints, the covering of wire ends with compound and wax and many other practices which are relics of the past. It is the purpose of this paper to outline the simplest forms of treatment which may be applied to either simple or complicated fractures of the mandible.

Anatomy If the thickened portions at the ends of a horseshoe were longer we would have a rough model of the mandible. If these ends were hung between two slings, the outer band of each sling would represent the masseter, and the inner, the internal pterygoid. Between them they support

the ramus of the mandible and act to pull the lower against the upper jaw. These two muscles are like a pair of horses attached to the wagon whipple-tree. The temporal muscles likewise pull the mandible upward. The external pterygoid acts to protrude the lower jaw.

If we combine the action of these muscles, the pull on the shorter fragment, when the fracture is at the angle, is an arc upward and forward (Fig 1). The depressors of the jaw are attached to the anterior portions of the body. Thus we see that the posterior fragment is always pulled upward and forward, the anterior fragment downward and backward.

Directional plane of fracture It is also of importance whether the line of fracture is from above to below, backward or forward. If in a unilateral fracture the plane of cleavage is forward, by its very nature the posterior fragment will support the larger anterior one (Fig 2). If on the other hand, the direction is backward there is nothing to prevent the shorter fragment from being dragged upward until the mandible strikes some portion of the upper jaw (Fig 3). Many other elements occur, such as the irregularity of the line of fracture and the position of projecting spurs, teeth in the line of fracture, or, occluding teeth. These all make the problem more complicated.

Fig 1 Direction of muscle pull. Arrow 1, direction of pull of the masseter and internal pterygoid. Arrow 2, direction of pull of external pterygoid. Arrow 3, direction of pull of the temporal muscle. Arrow 4, direction of combined pull of all three. Arrow 5, direction of combined pull of the infrahyoid and suprahyoid groups and the digastric and the platysma.

Fig. 4. The posterior fragment is being pulled in an arc upward but its direction of plane supports the anterior segment.

For many years we have stressed two principles in the care of fractures of the mandible—simplicity in plan of immobilization and prompt reduction. The importance of these basic facts will be shown later. Recent papers tend to lose sight of the fact that complicated splinting causes a loss of time in reduction of the fracture which is often detrimental to the patient. They also involve a costly splint not readily available to clinic patients. The surgeon unfamiliar with the mechanism of such splints is often at a loss to apply them and disturbances of occlusion are frequently the end result.

Early reduction. One of the most important lessons which we have learned is the importance of prompt reduction and the necessity for early immobilization. It is for this reason that we illustrate (Fig. 4) a method of application of simple bandage and adhesive with elastic traction which effectively holds the mandible immobilized. This simple method, devised by Karanjian, is in keeping with the principle that, to be effective treatment must be simple and applicable with the smallest number of special materials and instruments.

Intermaxillary wiring. The simplest form of fixation is intermaxillary wiring. A button serves as a hook to which intermaxillary elastics are applied. By gradual traction elastic force reduces a fracture to proper alignment and holds the segments in position. Very few special instruments are required to wire a fractured mandible. We use a 3 gauge annealed brass wire. However many people prefer a finer gauge. For lighter gauge we use stainless steel. Thick blunt needleholders are very useful for applying the button. A pair of wire cutters such as are used by electricians are useful and also a small pair of scissors used by dentists known as crown and bridge scissors.

These buttons differ from the ordinary hook in that there are no free ends to scratch the cheeks or lips. They require no covering of wax or com-

Fig. 5. The posterior fragment will be pulled upward and less is unsupported the anterior segment.

pound. They are sufficiently stable to withstand any amount of elastic pull without buckling. They are so shaped as to retain the elastic band without its slipping off. The strands are so uniformly twisted that there is very little danger of the wire breaking even if it becomes necessary to tighten the button at a later visit.

Intermaxillary elastics have been used for many years in orthodontia. In the latter part of the 19th century there was a bitter controversy as to the originator of the intermaxillary elastic as a corrective measure for malocclusion. There is still some debate as to whether Case or the elder Baker first described the method. The use of these elastics in the treatment of fractures of the mandible however owe their popularity to Karanjian who, returning from the First World War used and taught their use as early as 1919. A recent description in the literature adds little to what has long been known concerning the use of intermaxillary elastics. It leads one to believe that the method therein described is a new method. This is incorrect, inasmuch as the principle is old, and the method has been used by many of us for two decades more or less.

Method of applying button. Figures 5 and 6 show the method of applying the intermaxillary button, with the use of a four strand brass wire, 23 gauge. The wire is passed through the interdental embrasure from the buccal to the lingual surface on the tooth and then is passed back to form a loop about a tooth which has been selected because of its strategic location and suitable shape. A second loop is likewise passed about an adjoining tooth. The wire is grasped only at its end since the scratch of the hemostat weakens it sufficiently so that breakage is liable to occur. A needleholder of the short variety grasps each of the four strands. The wire is grasped parallel to its long axis and then by traction the length of the four strands

Fig. 4 Method of application of simple bandage and adhesive with elastic traction which effectively holds the mandible immobilized

equalized. Grasping the four needleholders together and applying traction while the assistant supports the broken bone the needleholders are twisted simultaneously while traction is applied. It is customary to twist the wires always in the one direction, i.e., clockwise, so that should further adjustment by another operator be necessary, he may assume that the wires have been systematically twisted. While the wires are twisted that portion of wire which envelops the tooth is adjusted so that it lies at the cemento-enamel junction where there is a small depression.

As soon as the strand or rope begins to buckle under the twisting motion, the twisting ceases. The twisted strand is then cut one inch from the beginning of the twisted portion, the four ply strand is then grasped with one needleholder. With a circular sweeping motion the rope is then wrapped around to form a complete loop and then is wrapped a second time, the second loop being placed under the first thus burying the free end and preventing it from scraping the soft tissues

of the cheek or lip and from cutting the elastics. The completed button is easily accessible and readily kept clean. It is firm and unyielding, its stability and ease of application makes the standardization of its application worth-while. For ordinary fractures two pairs of such buttons placed opposite each other in each premolar region, are sufficient to keep the mandible immobilized when the buttons are held together by elastics.

However, when in order to secure proper alignment it is necessary to produce traction in one direction or another and the teeth are present, this is easily accomplished by the addition of one or more buttons. In such event the button may be used as an attachment for elastics and as a guy pulley over which the elastic rides to produce force in the desired direction.

The use of elastic force presumes some experience in the practice of orthodontia. Considerable harm may result if teeth are used which are unopposed by antagonistic teeth for, although

Fig. 12. The bottoms are shown connected with short elastic band.

this traction is gentle, it is continuous and such a force is tremendous enough so that teeth can be completely lifted from their sockets in 24 hours. Should such an accident occur the wire and elastics should be promptly removed and rest will encourage the tooth to return to its original position.

In fractures of long standing where considerable deformity exists, 48 hours suffice to draw fragments,

although bound down by fibrous adhesions, to their proper alignment. The one rule without exception is that no tooth or group of teeth without occluding teeth in the opposite jaw should ever be used to support a bottom to which elastic traction is applied.

The most important guide to proper alignment is the occlusion. However there are several misleading factors about the meeting of the teeth of

one jaw with those of the other. The patient may have had an abnormal occlusion before the fracture, in other words he may have had a protruding or a retruding jaw. If there was protrusion of the mandibular teeth we occasionally have attempted to correct such a protrusion if this could be accomplished with benefit to the masticatory apparatus.

It sometimes occurs that after considerable effort in attempting proper reduction some space still exists between the anterior teeth. It must be remembered that pipe smokers wear teeth down so that there is often a space for the pipestem. This can be misleading.

The buttons are connected with a short elastic band which may be seen in Figure 12. In event that no elastics such as are used in orthodontia are available one may make his own short elastics. A knot may be tied in a long elastic, or bands may be cut from rubber tubing. The band need not be wrapped more than twice.

It is not necessary to fix the jaws so that it is impossible for the mouth to be opened. On the contrary, it is only necessary to hold the jaw in occlusion without force. The sudden forceful opening, as in yawning or sneezing, does no harm. We believe with Kazanjian that the ability of the patient occasionally to open the mouth a little stimulates healing. Intermaxillary elastics have other advantages. They are readily replaced without affecting the wiring or causing pain, thus permitting frequent examination of the mouth. This allows one to remove the wiring at the earliest possible moment, thus eliminating the old standard term of fixation for long periods. It also allows frequent and thorough cleaning of the oral cavity. In case a general anesthetic has to be administered, elastics need not be applied until after the patient has recovered sufficiently so as to preclude the risk of postoperative nausea. If there has been great displacement and immediate immobilization has been delayed because

of complications, as in the presence of head injuries, the elastic will by its constant though gentle force reduce without trauma the fragments to proper alignment. In epileptics, who frequently fracture the mandible, the elastics are so quickly removed as to be of great value. Further, in those cases in which the wiring needs to be modified from time to time the elastic simplifies matters a great deal.

CONCLUSION

Responsibility attending the care of fractures of the mandible has increased. No longer can the general surgeon be content with union regardless of resulting occlusion, no longer can the dentist be satisfied with union regardless of the number of teeth sacrificed, no longer can the oral surgeon be content to wire the mandible for long periods of time while his patient goes on losing weight and feeling like a muzzled dog.

Properly immobilized fractures of the mandible need not be fixed for the long periods that the textbook prescribes. We have many cases which have been immobilized for less than 15 days.

The intermaxillary elastic presents a method of immobilization which is simple and inexpensive and easily applied. It has the advantage of allowing frequent inspection and cleaning of the teeth. It may be readily applied, if a general anesthetic has been given, after the patient awakens, thus avoiding the danger of nausea. It permits enough physiological movement to encourage healing. It prevents trauma to the teeth as in sudden yawning. It permits in the latter days of fixation the ingestion of semi-solid foods. While ingenuity in the application of the various devices at the disposal of the attending general or oral surgeon is not only desirable but necessary, still the practitioner who sees only occasional fractures of the mandible would do well to acquaint himself with certain standard forms of treatment for the usual forms of fractures of the mandible.

PREVENTION OF WOUND DISRUPTION WITH THROUGH AND THROUGH SILVER WIRE STAY SUTURES

CRANSTON W. HOLMAN, M.D., and JOHN H. FICKEL, M.D. New York, New York

THE failure of abdominal wounds to heal properly and the resulting complications—wound disruption, infection, and post-operative hernia—still remain a serious problem. Most recent articles on the subject are concerned primarily with the various factors influencing wound healing, such as location of the incision, the suture material used, type of operation, dietary deficiency, imbalance of blood constituents, and the presence of jaundice, malignancy, or infection, rather than with the method of closure of the wound.

We wish to describe a method of closure that has proved entirely satisfactory in preventing disruption of wounds. It consists in the use of through-and-through silver wire sutures in addition to complete closure of the wound in layers.

The patients included in this report were operated upon and followed during the past 8 years at the New York Hospital, and in all, major operative procedures were performed with the use of longitudinal rectus incisions. This study would seem to indicate that the most important single factor in evisceration is the type of closure, since separation of the wound has been avoided by the use of the closure to be described.

Needless to say its efficiency in relation to postoperative infection and hernia depends in large part upon the strict observance of the cardinal principles of surgery: asepsis, complete hemostasis, and gentle handling of tissues. For full discussion of additional factors influencing wound healing, other papers may be consulted (1, 6, 7, 8, 11, 13, 16, 7).

During the past 10 years several reports (2, 3, 4, 9) have given adequate statistical reviews on the subject of evisceration from the point of view of suture material, type of operation, and location of incision. These observers have found the incidence of wound disruption to range from 1 to 3 per cent, with a mortality varying from 18 to 50 per cent, in spite of the various types of wound closure. However, Kennedy (10) in 1928 reported very satisfactory results with

through-and-through closure in which all worms but was used. Likewise, Rekl, Zinninger, and Merrell (14) in 1933, reported a method of abdominal closure with through-and-through silver wire and demonstrated that this closure was of particular value in patients who had serious intra-abdominal traumatic injuries. In their hands there was no instance of necrosis in the 334 cases operated upon. However, there are no technical objections to this simple through-and-through closure. One is the tendency for the wires to be closed so tightly that, with the development of postoperative edema of the wound, the wires cut into the tissues and the subsequent pressure necrosis causes pain and a high incidence of infection. Second, it is impossible to approximate the various layers accurately and, therefore, the incidence of postoperative hernia is high. In an effort to eliminate these objections a modification in the technique has been introduced, i.e., the closure of the wound in layers, in addition to the type of through-and-through silver wires. Undoubtedly this closure has been used from time to time in various clinics, but it has not received enough emphasis to be accepted as a routine in certain types of patients. This closure should not, of course, be used in all types of cases; rather its use should depend upon the operation and the pathology and the age and condition of the patient. Since through-and-through silver wire with closure in layers requires more time, it cannot entirely replace simple through-and-through closure in those patients in whom rapid closure is necessary. Likewise, the latter is the ideal method for repair of disrupted wounds.

Following is a description of the type of closure advocated. As shown in Figure 1, the silver wires (30 gauge) are inserted straight through all layers of the abdominal wall, including peritoneum, about 1 inch from the skin edge and placed about 3 inches apart. An atraumatic needle is used in order that the silver wire can be introduced easily and without injury to the tissue. If such a needle is not available, large cutting-edge needle similar to that used for inserting tension sutures may be used if the short end of the silver wire is turned back and crushed together where it passes through the eye of the needle. Following the in-

Fig. 3

Fig. 4

section of the silver wires, the peritoneum is closed with a continuous suture of catgut for a distance of about one half to three fourths of the wound, and the viscera is approximated for a some what smaller distance (Fig. 3).

As shown in Figure 3, the silver wires for that portion of the wound that has already been closed

are then twisted down in place. It is important that the operator place his finger within the abdomen when the wires are being twisted down to prevent omentum or viscera from being caught between the silver wires and the peritoneum and the wires should be twisted 6 to 8 times to prevent their opening. With the exception of the

TABLE I.—TYPE OF CLOSURE

		No.	%	No.	%	No.	%
Through and through with closure in layers	104	10	9.6	4	3.8		
Simple through and through without closure in layers	106	27	25.5	16	15.1	6	5.7

*Since this report included only those patients who were dead (from these operations) and were included after operations, patients are excluded who died or who were lost to follow-up examinations. (Ginn and Moore (3) have reviewed all operations occurring in New York Hospital. Their percentage of operations for () through and through with closure per cent, () simple through and through per cent.

upper inch, the remaining part of the wound is then closed in layers, and, with the upper end of the wound still open, the remaining silver wires are twisted down in place. The upper part of the wound must be kept open until all the wires are twisted in place, so that the operator can keep one finger in the abdomen to prevent strangulation of the viscera between the silver wire and the peritoneum. After twisting down all the silver wires, the small remaining portion of the open wound is closed in layers, and the skin is approximated with interrupted fine silk sutures.

The most important feature of this closure is that the silver wires should not be closed too tightly. It should be possible to place one finger easily between the silver wires and the skin after the wires are in place. Small caliber suture material (chromic catgut No. 0 or silk) is preferred for the layer closure so as to reduce the amount of foreign body in the wound. Rubber guards for the silver wire may or may not be used. In the absence of infection, the wires may be removed safely on the fourteenth to sixteenth day where as, in simple through-and-through-closure, the wires should not be removed until the twentieth to twenty first day. After the use of any variety of through-and-through closure the complication of extension of infection from the wound into the peritoneal cavity has never been observed. There has been no wound disruption and, with the exception of silk closure, the incidence of postoperative infection and hernia is considerably less than in any other type of closure. (Table I)

It will be seen from Table II that the cases in which the two methods of closure were used were similar.

In clean cases—exploratory laparotomy cholecystectomy for chronic cholecystitis—in which the laparotomy wound was closed with silk, wound disruption, infection, and postoperative hernia occurred in less than 1 per cent. In a similar group of cases in which the laparotomy wound

TABLE II.—CONDITIONS FOR WHICH OPERATION WAS DONE

	Through and through with closure in layers		Simple through and through without closure in layers	
	No.	%	No.	%
Perforated peptic ulcer

Removal of reaction	16	14	5	
Exploratory laparotomy				
Miscellaneous	—		10	
	104		106	

was closed with catgut, wound disruption occurred in 2 per cent, infection occurred in 1 per cent, and postoperative hernia in 9 per cent. This comparison emphasizes the advantage of a silk closure of the clean wound when the closure is done by those familiar with silk technique.

CONCLUSIONS

It is not advocated that the closure described should replace all other types, particularly silk, but it can be used to great advantage in certain patients.

Its advantages are (1) a secure closure without fear of eversion; (2) elimination of the objections to simple through-and-through closure, with the results that the patient does not suffer from a painful wound, that the incidence of infection and postoperative hernia is greatly reduced, and that a satisfactory scar is obtained.

It is an ideal closure for (1) all patients on whom the gastro-intestinal tract has been opened, (2) patients in whom there is acute intra-abdominal infection, (3) patients who are old and debilitated whom it might be advantageous to get up at an early postoperative date. (4) patients who for one reason or another may have a delayed wound healing, with the possibility of wound disruption.

THE USE OF ALLOY STEEL WIRE IN THE CLOSURE OF ABDOMINAL WOUNDS

THOMAS E. JONES, M.D. EDWARD T. NEWELL, JR., M.D., and
ROBERT E. BRUBAKER, M.D. Cleveland, Ohio

SINCE the introduction of alloy steel wire by Babcock (1, 2) this material has been employed with increasing frequency at the Cleveland Clinic for the closure of abdominal wounds. The incidence of abdominal wound morbidity has been reduced to such an extent that we believe a further report of its use would be of interest. A technique of closure with alloy steel wire is presented, and the incidence of wound infection and disruption is contrasted with antecedent methods and materials.

The use of wire sutures in the closure of abdominal wounds is not of recent origin. Historical reviews have been presented by Kraissl in 1936, and by Kaufman, Johnson, and Lesser in 1939. Following the first reports of Babcock, a number of articles appeared in the literature describing the advantages of alloy steel wire sutures. Dambin closed the abdomen in two layers, the first including all planes except the skin and subcutaneous tissues which were included in the second. In his experience, the advantages of alloy steel wire were: (1) It was tolerated well by the tissues, (2) it could be used in the presence of infection, and (3) it produced solid closure and emprovements were rare. Complaints of discomfort from wire knots were infrequent. It was occasionally necessary to remove a suture which acted as a nidus for a draining sinus.

Wells closed the peritoneum and posterior fascia with catgut and the anterior fascia with interrupted alloy steel sutures. Jenkins, in reviewing the experience of Babcock, stated that a larger percentage of wounds healed by first intention and that alloy steel was the most satisfactory suture material for use in infected fields because there was no tendency to sinus formation. Kaufman, Johnson, and Lesser found that the incidence of wound infection in the repair of hernias was markedly reduced when alloy steel wire was used. Preston showed that the tensile strength of wounds sutured with alloy steel wire was greater than that of those closed with silk or catgut. Several cases were reported demonstrating the absence of a tendency to produce draining sinuses in the presence of an infected field.

From the Cleveland Clinic

One of the first clinical impressions of alloy steel wire used alone without stay sutures in the closure of abdominal wounds was the frequency of satisfactory healing, regardless of such adverse factors as carcinomatous, deep jaundice, and general cachexia. Disruption was rare, despite the fact that wire was used in all of the more severe abdominal operations when this accident was feared. Wound infection seemed to be reduced markedly.

In order to confirm or deny this satisfactory clinical appraisal of wire sutured wounds, separate studies were made to compare the incidence of wound disruption and infection with other methods of abdominal closure.

Wound disruption. From January 1, 1930, to January 1, 1940, a group of surgeons at the Cleveland Clinic performed 4,54 consecutive laparotomies with 44 disruptions, an incidence of 1.05 per cent. This compares favorably with most of the reports in the literature (3, 8, 9). Fifteen deaths in the 44 cases were attributable to disruption, a mortality rate of 34 per cent. The mortality rate from this accident is quoted in the literature from 8 to 53 per cent (3, 6, 8, 9).

A detailed study of these 44 cases revealed that more than half of the disruptions occurred in upper rectus incisions, and that the highest incidence was found in operations on the biliary tract. This is in accordance with the findings in the series reported by McIneny and Howes. The disruptions according to the locations of the incisions were as follows: upper rectus, 23; lower rectus, 7; upper midline, 6; lower midline, 5; other locations, 3; a total of 44.

Although it was difficult to obtain accurate information regarding the predisposing causes, abdominal distention with vomiting occurred to a fairly severe degree in 30 to 40 per cent of the cases. Wound infection and drainage of bile and pancreatic juices was the second major cause, and was found in 30 per cent. Because of the rapid digestion of the catgut, biliary and pancreatic drainage are probably of paramount importance in disruption of wounds closed with catgut, as compared to those closed with nonabsorbable sutures.

In view of the high incidence of disruption in upper rectus incisions, especially in those made for operations on the biliary tract, a consecutive series from January 1, 1937, to January 1, 1940, was selected for a comparative study of wound disruption with various types of closure and suture materials. In this period, 193 operations were performed by members of the surgical staff, with 11 disruptions, an incidence of 5.7 per cent. Of 54 wounds closed in layers with catgut alone, either continuous or interrupted sutures, 6, or 11 per cent, disrupted. In 58 cases the wounds were sutured with continuous catgut sutures to the peritoneum and posterior rectus fascia, and with interrupted alloy steel wire to the anterior rectus fascia. In this group 4, or 6 per cent, of the wounds disrupted. Buried interrupted figure-of-eight alloy steel sutures were used to close 81 wounds. No stay sutures were used. Only one disruption occurred with this type of closure, an incidence of 1.2 per cent (Table I). The fact that nearly all the severe cases with jaundice and malignancy of the head of the pancreas were found in the last group adds significance to the results.

Wound infection. The total experience with abdominal wound healing in combined abdominoperineal resections for carcinoma of the rectum done by one surgeon (T. E. J.) was reviewed, and the morbidity in various types of closure of the abdominal wound was compared. This operation was selected for study because of the high incidence of infection in wounds closed with catgut and supporting stay sutures.

In order that a strictly comparable series could be obtained, 256 consecutive cases fulfilling the following requirements were taken from a total series of 366 cases: (1) The operation was a one stage combined abdominoperineal resection, (2) the colostomy was brought out of the abdomen through a midline incision, and (3) the technique of the operation was the same. Two stage resections, inguinal colostomies, preliminary cecosto-

TABLE I — ABDOMINAL WOUND DISRUPTION IN OPERATIONS ON THE BILIARY TRACT¹

Suture material	No. cases	No. disruptions	Per cent
Catgut (all layers)	54	6	11.0
Catgut and alloy steel wire	58	4	6.9
Alloy steel figure-of-eight sutures no stay sutures	81	1	1.2

¹Comparison of Suture Material in 193 Consecutive Cases January 1937, to January 1940

mies, and cases in which death occurred, except those attributable to wound morbidity, were excluded.

This series classified itself, in chronological sequence, into 3 groups. In Group I (76 cases), the abdominal wound was closed in layers with catgut and reinforced with silkworm gut stay sutures. In Group II (64 cases), the peritoneum and posterior rectus fascia were closed with catgut and the anterior rectus sheath, with interrupted alloy steel sutures. Stay sutures were not used. In Group III (116 cases), the abdomen was closed with alloy steel figure-of-eight sutures alone, including all layers except the skin and subcutaneous tissues. Stay sutures were not used. In all of the groups the hemostatic ligature was fine No. 000 chromic catgut. The skin was closed with clips. No sutures were used in the subcutaneous tissues, even in obese patients.

Wound infections were clinically classified as slight, moderate, and severe. A small localized subcutaneous infection was considered slight. Definite abscesses superficial or deep to the anterior rectus fascia, but which healed before the normally expected hospital discharge, were classified as moderate. Infections which seriously endangered the life of the patient or prolonged hospitalization, or those to which death was attributable, were classified as severe.

As shown in Table II, in Group I, 27.5 per cent of the wounds became infected. Disruption occurred in 3 wounds, or 3.9 per cent, once because

Fig 3b

of infection and twice in the presence of apparent clean healing. Two of these patients died of peritonitis as a result of the disruption. In Group II infection developed in 14 per cent of the wounds. There were no disruptions. In Group III only 1 wound infection occurred, an incidence of 0.83 per cent. This occurred in the seventh case of the group. In the last 100 consecutive one stage abdominoperineal resections for carcinoma of the rectum, with midline colostomies and closed with alloy steel figure-of-eight sutures, there has not been a single infected wound.

No strictly comparable figures on the incidence of hernia in the 3 groups can be quoted, since the follow-up in Group III has not been of sufficient length of time but we have yet to see a hernia or weakness of the wound about the colostomy where wire figure-of-eight sutures were used.

TECHNIQUE

A method of closure of abdominal wounds with alloy steel wire employing Smead's stitch, is shown in the accompanying diagrams. A figure-of-eight suture passes first through anterior fascia, muscle, posterior fascia, and peritoneum (Fig. 1a) and again through the anterior fascia in the

same direction (Fig. 1b). After three-fourths of the wound is closed, the remaining fourth is loaded with the first part of the interrupted stitch (Fig. 2). Each suture is then completed in turn.

The wire ends are cut flush with the jaws of a hemostat which is clamped snugly against the knot (Fig. 3a). The hemostat is then rotated 90 degrees, turning the ends downward (Fig. 3b). A smooth knot is thus presented to the subcutaneous tissues, in which no sutures are placed. The skin is closed with metal clips.

Certain technical details in regard to the type of suture and the handling of the wire itself must be adhered to: (1) The proper amount of tension must be exerted in tying the suture to approximate, but not constrict, the tissues. (2) The knot must be square. (3) The ends of the wire must be turned down carefully. (4) kinking must be avoided since the wire will break at this point. Wire handles differently from silk or catgut but, with experience, it may be used with equal facility.

As the figure-of-eight sutures are pulled taut, each plane of the wound is well approximated. No more accurate closure can be accomplished by sutures in layers. Digital palpation of the peritoneum shows a perfectly smooth wound surface.

This stitch was devised by Dr. Louis Smead, of Toledo, Ohio, during his residency in surgery under Dr. John F. Keen, Jr. of Baltimore. It has been advised by personal communication that description of it has not been published by him.

ADVANTAGES AND DISADVANTAGES

During the past 3½ years, alloy steel wire alone has been chosen with increasing frequency for the closure of abdominal wounds by the members of the surgical staff of the Cleveland Clinic. It is now used extensively in operations on the biliary tract, for benign lesions of the stomach and duodenum, and routinely in operations for gastro-intestinal and other abdominal malignancies in both the upper and lower abdomen.

The routine use in gastro-intestinal malignancies deserves note. The marked decrease in wound complications has been a major factor in the reduction of postoperative morbidity and hospital mortality. The series of combined abdominoperitoneal resections presented typifies the entire experience.

Most clean laparotomy wounds can be closed satisfactorily with catgut, silk, or cotton. However, when actual or potential wound infection exists, or when disruption is feared, we believe that better results can be obtained with steel wire. Steel-closed wounds heal with very little tissue reaction to the suture material. In this respect steel is similar to silk, but it has an added advantage in that the production of chronic draining sinuses is rare, even in the presence of a grossly infected field. The induration and grayish, necrotic foci about catgut is in sharp contrast to the clean, reactionless healing in the presence of wire.

The disadvantages of steel wire are few. Rarely, a suture will perpetuate a draining sinus. It has been necessary to remove sutures for this reason in only 2 instances. Occasionally, a patient with scanty subcutaneous tissue will complain of discomfort about a knot but it is a simple procedure to locate and remove the offending suture under local anesthesia.

We believe that alloy steel wire is indispensable in operations for gastro-intestinal malignancies, and so advantageous in many other procedures that its few disadvantages are greatly outweighed.

SUMMARY

1. The use of buried alloy steel sutures alone without stay sutures for the closure of abdominal

wounds has reduced wound morbidity to an extremely low incidence.

2. The incidence of wound disruption in operations on the biliary tract has been reduced from 11 per cent in closures with catgut to 1.2 per cent in wounds closed with alloy steel figure-of-eight sutures alone.

3. The incidence of infection in abdominal wounds in combined abdominoperitoneal resections with midline colostomies has been reduced from 27.5 per cent with the use of catgut in layers and stay sutures to 0.85 per cent with the use of interrupted figure-of-eight alloy steel sutures.

4. A method of closing abdominal wounds with wire is presented.

ACUTE AND CHRONIC INTRA ABDOMINAL LYMPHADENOPATHY

ABRAHAM O WILENSKY M.D. F.A.C.S. New York, New York

LYMPHADENOPATHIES of one kind or another are well known to the profession in regional areas of the body other than the mesenteric area where their secluded position has served until recently to prevent sufficient examination and study. It appears that the adenopathies of the abdominal field are identical with those of other regions of the body—that the lesion may be acute or chronic and of varying degrees of intensity—that some lymphadenopathies in the mesenteric area are of maximum grade while others, the great majority of the instances, are apparently simple and more benign cases of mesenteric adenitis. It is the last group that we have especially under discussion. In some types the etiology is well known. In others it is still under discussion, and to these the term "non-specific" has been applied.

The term non-specific as used in this communication is intended to convey the thought that the essential cause of the glandular enlargement under discussion was not specifically known at the present writing or that the adenitis had a potential multiple form of etiology. The term might be better paraphrased as nonclassifiable. Except as an incidental matter unavoidably provoked by the discussion of nonspecific mesenteric adenitis, there will be no reference therefore to specific forms of lymphadenopathy—due either to a specific infecting agent such as those causing typhoid, tuberculous, leptic, or other disease, or to neoplastic change such as the forms of lymphosarcoma, or those bordering upon inflammatory or neoplastic disease such as Hodgkin's disease.

A previous communication summarized all available knowledge concerning the anatomy and physiology of the intra-abdominal lymph nodes, including the usual type of structural arrangement and its "normal variations." The normal functional processes (physiology) and the effects upon the latter of age, nutrition, environment, growth, etc., and of certain abnormal conditions of the body such as fever, anemia, etc., were all gone into exhaustively. It does not seem necessary to repeat this factual knowledge, and those interested sufficiently are referred to the original paper or to the standard works on anatomy and physiology.

It seems important, however, to comment again upon the variable size of the nodes when distinguishing between normal and abnormally enlarged glands and this factor is especially important in the long standing, chronic conditions. It seems that there are as yet no certain measures of the normal variation in size of the mesenteric and other lymph glands and that the lymphatic tissue and glands may be considerably more developed than have hitherto been assumed. In the previous study I pointed out the possibility that in many of the published cases the size of many of the observed intra-abdominal glands may have possibly been within normal limits and that, as a consequence, fundamental errors of diagnosis were possible in reference to any observed symptomatology in such lymph nodes.

A constant variable physiological fluctuation during the different phases of life occurs in the midst of relatively healthy periods. It is a non-specific phenomenon common to very many diseases. For instance fever has an effect on the lymph nodes which is characterized by decreasing the delivery phenomena of the lymph nodes into the peripheral circulation. This has recently been studied by Doan. Unless the period of sustained fever is unduly prolonged increased circulation and regeneration occurs fairly quickly and this can be measured in terms of the leucocytosis which follows.

The superlatively developed absorption function of the intestinal tract combined with the constant presence of bacteria in the intestinal lumen creates a situation in which the passage of bacteria from the bowel interior into the associated lymphatic vessels and glands must be considered an almost normal and physiological phenomenon. Although manifestations of the reaction of the host's defense mechanism against this continuous onslaught of bacteria (i.e. disease) are not apparent, it must be true that lymphatic enlargement will take place and in certain instances persist. In the ordinary stress of health and disease and under the proper circumstances, this fact would tend to complicate attempts at integration of the presence of mesenteric nodes into a given syndrome in which other pathology is not demonstrable.

WILENSKY INTRA-ABDOMINAL LYMPHADENOPATHY

differentiation between acute and chronic is sometimes more or less of an artefact, sometimes the chronic cases are simply those of succession of acute episodes has taken place by intervals in which the symptom is less intense or in which it has subsided even to the point where the symptom is tolerated so completely as to make the belief they have disappeared entirely. In case the chronic anatomical changes clearly characterize the pathological picture usually accounts for the peculiar percentages in Foster's series

ROENTGENOLOGY

Commonly roentgenographic study of the abdominal viscera—gastro intestinal series, etc.—

no abnormality

Under the usual normal conditions, roentgen observation shows that the stomach empties continuously and barium passes steadily in normal direction, reaching the cecum in 1½ to 2 hours. Each successive film shows progress distally the position of the head of the barium column. The segmental peristaltic movements flow smoothly and are promptly followed by normal relaxation of the intestinal wall. If there is delay in movement, the ileum should be seen in 9 hours. The barium mass in the normal intestine is usually continuous, that is, not broken up into separate small oval boluses. The length of normal, barium filled loops varies from 20 to 30 centimeters, and is usually 20 to 25 centimeters.

In association with acute symptoms Golden and Reeves observed the following manifestations of disturbed small intestinal physiology: "(1) localized spasm, i.e., narrowing of a small segment adjacent to the calcified node, either temporary following a peristaltic wave or persistent, (2) persistent generalized spasm of a group of small intestinal loops in the region of the diseased nodes, (3) delay in the passage of barium at the site of the calcified node, (4) delay in the emptying of the ileum for periods of over nine hours." In both the acute and chronic cases calcifications are sometimes visible roentgenographically. In the acute cases the coincidence is usually disregarded. In the chronic cases they are differently considered.

Golden and Reeves point out "the possibility that the roentgenographically observed disturbance of physiology in the intestine may be an explanation for the symptoms often associated with calcified mesenteric lymph nodes. The disturbances in small intestinal physiology include spasm and seemed to take place in loops of intestine

directly adjacent to calcified nodes." A questioning attitude concerning the relationship of roentgenographically demonstrated calcified abdominal lymph nodes and the symptom complex which an individual patient presents is necessary. This questioning attitude is advisable because it is not necessarily so that the one is responsible for the other.

ETIOLOGY OF INTRA-ABDOMINAL AND MESENTERIC LYMPHADENITIS

Specific forms of intra-abdominal and mesenteric lymphadenopathy are commonly parts of distinct clinical complexes such as typhoid fever, dysentery, etc. The protean nature of the etiological factors concerned in nonspecific forms of lymphadenopathy within the abdomen is well shown by their relatively enormous distribution. Some are related to loosely gathered clinical entities known collectively as the "rheumatic" group. Still others are related to various groups associated with generalized cutaneous manifestations including some of the exanthemas. A large group seems to be related to a preceding "catarrhal" or "throat" infection, and this seems to have some relationship to forms of glandular fever and infectious mononucleosis and to what is clinically known as abdominal grippé. Finally there is a group in which the lymphadenopathy cannot be clinically connected with any demonstrable preceding or accompanying lesion. Because of the latter fact the cases in the latter group have been associated in a still undemarcated and undifferentiated classification and are for want of a better nomenclature called nonspecific mesenteric adenitis.

Not always is the causative agent demonstrable in nonspecific mesenteric adenitis. In only a minority of the latter cases bacteria can be demonstrated in the glands, and the predominating organism is some strain of streptococcus. Occasionally other bizarre organisms can be cultured such as *Bacillus melitensis*. An unidentified virus has also been suggested as the causative agent but the correlation of this virus with that which might cause poliomyelitis has not been proved. No relationship can be demonstrated by the Frei test with lymphogranuloma venereum. Various parasites have been found to occur in the intra-abdominal lymph nodes and a causal relation cannot be established between them and acute nonspecific mesenteric adenitis, but in chronic mesenteric adenitis there might be some etiological connection in that the parasites might be intermediate factors in introducing other forms of bacterial infection.

factors may be accepted as more or less characteristic of this affection. It is difficult to say how frequent is this form of chronic lymphadenitis. In Foster's series of cases in which he has grouped acute and chronic cases, it seems remarkable that the percentage for the chronic cases is 64 as opposed to 8 per cent for the acute cases. My own experience is not large.

In the more advanced cases and in the group of older patients there is a tendency toward marked mimicry of other known symptom complexes there may be symptoms of dysphagia (Wakely) or symptoms suggestive of peptic ulcer (Thlemann, Lund Bler Keppler and Erkes, Davidovitch Ljunggren Golden and Reeves) of biliary colic (Alost, Pribram) of intestinal spasm (Schall) of constipation or diarrhea (Sternberg) of renal colic or hematuria (Schmieden Walker, Davidovitch, Golden and Reeves) or even of sciatica (Ljunggren). The commonest complex imitates very closely that which we customarily have known as "chronic appendicitis."

In this type of syndrome, more and more commonly as attention is being constantly focused on it, enlarged glands are the sole findings at abdominal explorations either performed frankly as such or done under mistaken diagnoses. Occasionally such glands are sufficiently large to be palpable before operation.

The differential diagnosis has commonly been most difficult in the chronic cases. Many factors must be considered, a general survey of which are

There are certain abdominal manifestations common in adults and practically unknown in infancy and early childhood, such as those of chronic gastritis, of ulcer and carcinoma of the stomach, of biliary colic, of gastric crises in tabes dorsalis, of movable kidney. Appendicitis is apparently very rare in the first and even the second year.

There are some abdominal syndromes that have the same significance and show the same characteristics at all ages, except perhaps in young children such as salpingitis, appendicitis, and renal colic.

3. Other abdominal manifestations occur wholly or predominantly in infancy or in early childhood. Nearly all of those occurring in infancy are produced by obstruction of a hollow viscus—pyloric stenosis, intussusception—or are associated with digestive abnormalities—colic. Later abdominal pain occurs with throat infections and with pneumonia but this is relatively rare. Chronic abdominal pain occurs with tuberculous spondylitis, with the chronic nonappendiceal forms of peritonitis, with tuberculous peritonitis, with rheuma-

tism and Henoch's purpura with the occasional case of worms, and lastly with enlarged inflamed mesenteric and retroperitoneal glands.

With modern methods and with adequate laboratory aid, it should not be difficult to make a differential diagnosis between urological, gall bladder stomach, and female pelvic disease. Cases of *bona fide* acute appendicitis in the vast majority of the cases should not escape one. In subacute and chronic cases of appendicitis, however the difficulties are great. The situation in regard to appendicitis may be summed up as follows:

a. The group in which delayed operation invariably resulted in cure. On these appendicectomy was not done in the acute stage of the various forms of a *bona fide* acute appendicitis. The symptoms continued for a variable length of time until a chronic phase was reached and the appendix was then removed. In such a case the usual condition found was a chronic abscess or a chronic hypertrophic appendicitis. In some cases the lesion resembled a nonspecific granuloma of the intestine.

b. A small group in which the pain resembled that of gastric and duodenal ulcer but was referred to the appendix despite the fact that no pathological lesion could be demonstrated therein. In almost countless experiences this has been proved to be a delusion: the pain has no demonstrable relation to the appendix or to the stomach and duodenum, it has no other demonstrable basis, and in practice such a pain is most difficult to handle as it does not react to any therapeutic agent employed.

c. A group in which appendicectomy and other forms of therapy failed to relieve episodes of pain or continuous annoying sticking pains in the right side of the abdomen, the symptoms simulating no well known complex.

In later years it has seemed to be more and more true that many if not all of the patients in groups b and c, had some form of psychoneurotic basis or background for the clinical picture. This conclusion was frequently confirmed by the presence of corneal and pharyngeal anesthesia and by excessive activity of the knee and thigh tendon reflexes.

d. A large group in which an obliterated appendix had previously been removed. Commonly removal was associated with somewhat hypertrophic change in the terminal nerves of the appendix, which was labeled a *neuroma*. Recurrence of symptoms was almost the rule and I am convinced that such anatomical changes are of a regressive involutionary character and cannot produce abdominal pain.

The differentiation between acute and chronic cases is sometimes more or less of an artefact, because at times the chronic cases are simply those in which a succession of acute episodes has taken place separated by intervals in which the symptomatology is less intense or in which it has simmered down even to the point where the symptoms are tolerated so completely as to make the patient believe they have disappeared entirely. In either case the chronic anatomical changes eventually characterize the pathological picture. This probably accounts for the peculiar percentage figures in Foster's series.

ROENTGENOLOGY

Commonly roentgenographic study of the abdominal viscera—gastro-intestinal series, etc.—shows no abnormality.

Under the usual normal conditions, roentgenographic observation shows that the stomach empties continuously and barium passes steadily in the normal direction, reaching the cecum in $1\frac{1}{2}$ to 4 hours. Each successive film shows progress distally in the position of the head of the barium column. The segmental peristaltic movements flow smoothly and are promptly followed by normal flexible relaxation of the intestinal wall. If there is no delay in movement, the ileum should be empty in 9 hours. The barium mass in the normal small intestine is usually continuous, that is, not broken up into separate small oval boluses. The width of normal, barium filled loops varies from 1.5 to 3.0 centimeters, and is usually 2.0 to 2.5 centimeters.

In association with acute symptoms Golden and Reeves observed the following manifestations of disturbed small intestinal physiology: "(1) localized spasm, i.e., narrowing of a small segment adjacent to the calcified node, either temporary following a peristaltic wave or persistent, (2) persistent generalized spasm of a group of small intestinal loops in the region of the diseased nodes, (3) delay in the passage of barium at the site of the calcified node, (4) delay in the emptying of the ileum for periods of over nine hours." In both the acute and chronic cases calcifications are sometimes visible roentgenographically. In the acute cases the coincidence is usually disregarded. In the chronic cases they are differently considered.

Golden and Reeves point out "the possibility that the roentgenographically observed disturbance of physiology in the intestine may be an explanation for the symptoms often associated with calcified mesenteric lymph nodes. The disturbances in small intestinal physiology include spasm and seemed to take place in loops of intestine directly adjacent to calcified nodes."

A questioning attitude concerning the relationship of roentgenographically demonstrated calcified abdominal lymph nodes and the symptom complex which an individual patient presents is necessary. This questioning attitude is advisable because it is not necessarily so that the one is responsible for the other.

ETIOLOGY OF INTRA-ABDOMINAL AND MESENTERIC LYMPHADENITIS

Specific forms of intra-abdominal and mesenteric lymphadenopathy are commonly parts of distinct clinical complexes such as typhoid fever, dysentery, etc. The protean nature of the etiological factors concerned in nonspecific forms of lymphadenopathy within the abdomen is well shown by their relatively enormous distribution. Some are related to loosely gathered clinical entities known collectively as the "rheumatic" group. Still others are related to various groups associated with generalized cutaneous manifestations including some of the exanthemas. A large group seems to be related to a preceding "catarrhal" or "throat" infection, and this seems to have some relationship to forms of glandular fever and infectious mononucleosis and to what is clinically known as abdominal gripe. Finally there is a group in which the lymphadenopathy cannot be clinically connected with any demonstrable preceding or accompanying lesion. Because of the latter fact the cases in the latter group have been associated in a still undemarcated and undifferentiated classification and are for want of a better nomenclature called nonspecific mesenteric adenitis.

Not always is the causative agent demonstrable in nonspecific mesenteric adenitis. In only a minority of the latter cases bacteria can be demonstrated in the glands, and the predominating organism is some strain of streptococcus. Occasionally other bizarre organisms can be cultured such as *Bacillus melitensis*. An unidentified virus has also been suggested as the causative agent, but the correlation of this virus with that which might cause poliomyelitis has not been proved. No relationship can be demonstrated by the Frei test with lymphogranuloma venereum. Various parasites have been found to occur in the intra-abdominal lymph nodes; a causal relation cannot be established between them and acute nonspecific mesenteric adenitis, but in chronic mesenteric adenitis there might be some etiological connection in that the parasites might be intermediate factors in introducing other forms of bacterial infection.

PORTAL OF ENTRY OF THE CAUSAL AGENT

The portal of entry for the causative agent of nonspecific mesenteric adenitis is only on rare occasions the appendix and this can happen only because of some anatomical abnormality of the lymphatic drainage pathways of the appendix. More commonly the portal of entry seems to be related to catarrhal or throat infections and then nonspecific mesenteric adenitis is least commonly a manifestation of a hematogenous mechanism or more commonly the causative agent is swallowed from the oropharynx and passed along to the terminal ileum from which local absorption occurs. Most frequent of all the nonspecific mesenteric adenitis is a local absorption effect from some local nondemonstrable lesion in the ileal segment of the alimentary canal. It can be safely assumed that this includes various forms of transient enteritis and other surface infections, various gross and microscopic injuries, and other forms of physical and chemical trauma.

In this most common mechanism the similarity to the ordinarily observed phenomena in cervical adenitis is absolute. In either case local injuries and infections permit the passage of the causative agent to the appropriate lymph nodes. The mechanism is based upon an exact duplication in either position of the anatomical arrangement of the local lymphadenoid tissue in the wall of the alimentary canal and of the corresponding lymph nodes. And the heaping up of extraordinary collections of lymphadenoid tissue in the wall of the alimentary canal at either of these locations is remarkable and seems important from an etiological and mechanistic viewpoint.

I wish to emphasize the importance of the terminal ileum as a regional portal of entry for the causal agent for many and perhaps most of the cases of simple nonspecific mesenteric adenitis. The opportunities for absorption of any causal agent are remarkable including that associated with the normal digestive functions and that predicated upon the occurrence of local points of injury. The passage of any provocative causal agent from the oral cavity to the terminal ileum is a constant occurrence and it is most remarkable that these forms of infection do not occur with greater frequency.

THE LYMPHADENOID TISSUE

The important rôle played by the lymphadenoid tissue of the alimentary canal is only correctly appreciated when one realizes the great frequency with which it becomes involved in the various diseases known to clinical medicine. The tangible knowledge indicates an astonishingly large inci-

dence of involvement of the mesenteric glands in typhoid and paratyphoid fever. In the various forms of bacteremia, in status lymphaticus, in tuberculosis, rarely in leues and actinomycosis, more commonly in the various blood dyscrasias, in a case of agranulocytosis reported by Felsen, and in the various forms of colitis, enteritis, and dysentery. This list does not include the various forms of malignancy and such borderline lesions as Hodgkin's disease. As indicated previously, in some of these, such as typhoid fever, the mechanism of development and of the transit of the infection is well known. The newer anatomical knowledge in colitis and dysentery indicates a fairly close approximation to the latter.

In all forms of diarrheal disease in infants and children—infantile diarrhoea, cholera infantum, acute ileocolitis in infants and children, summer diarrhoea, etc.—the process seems centered in or to show a predilection for the vicinity and substance of the intestinal lymphadenoid nodules and is especially marked in Peyer's patches. Apparently all of these forms begin as surface infections and reach down into the substance of the intestinal wall as the pathological process proceeds. The spread into the wall occurs along the lymph channels into collections of lymphadenoid tissue—solitary follicles, Peyer's patches. Wherever in the various publications (Holt, Felsen, etc.) particular attention is paid to this element and the findings recorded. It is astonishing to see how much and how often other specific mention is made of the localization about and the involvement of Peyer's patches. In this regard the differentiation between small and large intestine is merely quantitative one and depends upon the distribution of solitary and aggregated collections of lymphadenoid tissue—solitary follicles—Peyer's patches. In the small intestinal cases, it is common to find the lesion localized for the most part or limited to the lower ileum where the lymphadenoid tissue abounds to such a large extent in the intestinal wall. The spread into and the involvement of the adjacent tissues of the intestinal wall becomes visible only with the prolongation of the illness and its anatomical development.

So-called catarrhal infections are commonly associated regionally with the upper reaches of the alimentary canal and have been previously referred to under the general nomenclature of throat infections. For the most part these occur anatomically in relation to the lymphadenoid apparatus of the tonsils and adenoids and their secondary involvements in the cervical glands. They are commonly said to be surface infections. Whether such catarrhal infections

can occur deep down in the ileum and originate in and about the Peyer's patches is something which is apparently beyond the present available powers of demonstration, but certainly it is so that in simple mesenteric adenitis without other demonstrable lesions there is identical symptomatic and anatomical manifestations to those similar lesions that originate in the oropharynx. The interplay of "throat" infection with abdominal symptoms as indicated in this communication is more than a mere coincidence and is remarkable.

INTRA-ABDOMINAL LYMPHANGITIS

Our entire conception and assumption regarding the clinical importance of intra-abdominal lymphangitis and lymphadenitis must be revised. Up to the present these have been accepted too lightly and in an indefinite way and have not been adequately correlated with the observable subjective and objective symptomatology.

Pribram's observations as to lymphangitis in the mesenterium will deserve attention. Pribram (1926) emphasized the occurrence of lymphangitic alterations strongly, and described the appearance of chronic lymphangitis in the mesenterium emanating from insignificant—possibly not even noticeable—inflammatory alterations in the intestinal wall. According to Pribram the altered lymphatic vessels in the mesenterium may be observed as strings, even of the thickness of the radial artery. Pribram considers that the glandular alterations he has observed, now as acute enlargements, now as cicatricial processes with periadenitis, play a less predominant symptomatic rôle than lymphangitis. Pribram's interpretation has followed the commonly accepted assumption that the appendix was at the bottom of the trouble, but he notes that even after appendectomy the process showed a tendency to successive spreading and occasional recrudescence, leading to shrinking of the mesenterium and diffuse adhesions in different parts of the abdominal cavity, owing to the spreading of the infection in the subserous lymphatic plexus. The lymphatic vessels of the portal fissure become infected in the same way, resulting in the pericholecystitis, periduodenitis, and possibly in a consequent spread of the infection to the pancreas. Pribram attaches great importance to the mesenteric alterations he describes. They are, he thinks, often the cause of discomforts after appendectomy in cases of chronic appendicitis and are a link with other more or less obscure abdominal affections, e.g., pancreatitis and peptic ulcer. Appendectomy and cholecystectomy, respectively, at an early stage are recommended also in clinically slight cases as prophylactic measures.

In spite of the fact that some of Pribram's conclusions are, perhaps, rather far fetched, his opinion regarding the clinical rôle and importance of intra-abdominal lymphangitis, and regarding the diagnostic importance of any residual anatomical alterations in connection with any preceding organic abdominal affection, should be well taken. Evidences of the latter abound on all sides, and I am sure that almost every operating surgeon can well remember many instances during a laparotomy in which evidences of preceding lymphangitis of greater or lesser extent were observed in the absence of other demonstrable lesions. As a matter of fact many of the instances in my own experience were explorations in which we were puzzled by the subjective symptomatology and the laparotomy was undertaken in an effort to find adequate cause and cure for the symptoms. Up to the present time these have been accepted, sometimes as being anatomical variations—adhesions—at other times as being evidences of some previous condition which we were too ready to accept as having no relation to the observed symptoms, but as one looks back upon his experience he can easily remember cases in which these areas directly connected with contiguous lesions in the bowel wall. To take an exaggerated example, a carcinoma or a diverticulitis of the sigmoid commonly presents visibly enlarged lymphatic channels and, in later cases, a secondary shriveling of the mesosigmoid, with enlarged palpable lymph nodes nearby. Nevertheless, it seems now that these opinions must be revised even if we are not quite ready to accept the assumption *in toto* that all of these patients suffer from such abdominal discomforts really suffer from some form of lymphangitis or adenitis. And in cases of this kind, the importance of the primary organic infection as a point of origin for any secondary lymphangitis and lymphadenitis must not be lost sight of as contributing in some part at least to the observable symptomatology.

PATHOLOGY

In acute cases intra-abdominal lymphadenopathy occurs (1) as part of a generalized adenopathy, (2) as an initial involvement of one group of glands with spread to other groups, and (3) as limited to one anatomically differentiated group of glands. Even though chronic adenopathies may begin in any of these ways, the rule is to find only one group of glands involved, although exceptions occasionally occur.

Evidences of any distinct inflammatory process are not always present in the glands which are removed for study. In general, all kinds of simple

hyperplasias and sinus catarrhal exudates are seen and in severe cases purulent fusions and frank abscess formation as well. In severe cases local and general forms of peritonitis occur either by transudation of infectious material or by perforation of glandular abscesses.

In the chronic cases the immediate impression is that lymph gland enlargement is due to some long standing—chronic—form of infection of immediately undeterminable etiological classification. The observable anatomical facts are frequently and commonly not easy to differentiate and classify. Commonly one questions the rôle of tuberculosis or one suspects an early stage of Hodgkin's disease or other form of lymphatic malignancy: or it may happen that one is not impressed with the presence of enlarged glands and dismisses them lightly as of no importance. And usually in the absence of any final conclusion the patient is referred to the follow-up clinic for further observation and study.

In both acute and, more commonly in the chronic cases giant cell systems are seen in the histological sections of some of the cases. Such giant cell systems or collections of epithelioid cells approach and are frequently indistinguishable from those of tuberculosis but the tendency to regress without excessive scarring and the absence of caseation and acid-fast bacilli in them, contradict this. They are usually found associated with severe infection of the alimentary canal accompanied by necrosis. Inasmuch as in the very much milder form of nonspecific adenitis only a hyperplastic condition is present in the lymph nodes, indicating a correspondence of intensity of process between the lymph node picture and the picture in the intestinal tract, it must be assumed that the differences in anatomical picture is caused by the different gradations of toxicity of the etiological cause or of the size and intensity of the dose of the causal agent which is delivered.

One must also assume that the so called tubercle arrangement can be found not only in specific forms of infection, like tuberculosis, and lues, but also in forms of nonspecific infection in which up to the present time no definite cause can be assigned. It might very well be that this sort of picture represents the anatomical progression between simple forms of lymphadenopathy on the one hand and those of definitely specific anatomical pictures, which are customarily correlated less often with lues and especially with tuberculosis. Undoubtedly this also explains the confusion which occurred, not only in the earliest historical period of this subject, but even in later times, in

classifying all forms of enlargement of the mesenteric glands as tuberculous.

Mixed infection in tuberculous adenitis plays a very important rôle. It is commonly noted in the neck. Less frequently it is observed in the abdomen. In such mixed infections the anatomical picture sometimes is vague enough to make it difficult to say definitely whether the infection is originally tuberculous even though from clinical experience we may feel fairly sure that it is. Mixed infection of tuberculous glands are commonly severe enough to cause sufficient destruction to wipe out a good deal of the glandular structure so that the original tuberculous formation cannot be visualized.

RELATIONSHIP OF TUBERCULOUS INFECTION TO ACUTE AND CHRONIC INFLAMMATORY ENLARGEMENT OF THE INTRA-ABDOMINAL LYMPH NODES

In many of these people there is a history of heavy exposure to tuberculosis in childhood, but at the time of examination evidences of tuberculosis are not obtainable either by physical examination or by laboratory tests. In girls there is sometimes more than the usual rise in temperature at the time of menstruation.

Physical examination generally shows thin nervous young woman with a temperature around 100 degrees F or less, and a tender abdomen. Sometimes an appendectomy has already been done at other times it is presented as the question at issue. Roentgenographic evidence of disease of the stomach gall bladder and colon will not show anything abnormal, but occasionally calcified intra-abdominal lymph nodes are visualized.

Many an anatomical diagnosis of tuberculous mesenteric adenitis has been, and continues to be, made upon the roentgenographic demonstration of calcifications in the general region of the lower right abdominal quadrant. Pribrium was of the opinion that glandular calcifications might set in as a final stage of any pathological process without having been preceded by a tuberculous infection. Noeske had also subscribed to the same opinion. In the former case, none of the observers had any method of establishing reliable proof except for the demonstration of the presence of tubercle bacilli which was frequently not valuable. In the latter group the contrariwise opinion was held because tubercle bacilli were not demonstrated and because of other clinical and collateral knowledge.

That inflamed and enlarged mesenteric and retroperitoneal glands, non-tuberculous in origin, do occur is well known. In his recent paper on

abdominal pain in children, Hutchison emphasized the importance of enlarged glands in the causation of abdominal pain in children

Personally, I am convinced from all of my experience, that although tuberculous infection is well known and has been adequately proved to exist in the mesenteric and other abdominal lymph nodes, there are also other cases of chronic inflammatory enlargement of these nodes with and without necrosis and with or without calcification, which are not caused by infection with the tubercle bacillus

COMPLICATIONS

The following complications have been reported in both acute and chronic intra-abdominal lymphadenitis (1) massive invasion of the entire lymphatic chain, (2) suppurative periadenitis with infiltration of the mesentery or with the formation of a tumor-like mass, (3) intra-abdominal abscess resulting from the rupture of a suppurative gland with or without local and general forms of peritonitis, (4) erosive bleeding from a large intra-abdominal blood vessel, (5) thrombosis of some vessel in the mesenteric plexus, (6) compression of a hollow viscus by enlarged inflamed glands, (7) intestinal obstruction, (8) obstruction of the biliary ducts, (9) compression of the ureter with secondary hydronephrosis

SUMMARY AND CONCLUSIONS

A number of concepts have resulted from this factual review

1 A very important common denominator of all of this aggregation of facts is the age factor. It is apparent that all of the conditions herein reviewed with which general and mesenteric lymphadenopathy is associated occur in the period of life beginning with childhood and extending with less frequency up to the adolescent period. It appears from this that during this period of life the lymphatic apparatus of the human being is under continual and variegated stress and is most apt to undergo pathological changes

2 The streptococci are most frequently associated with the various forms of so called non-specific lymphadenopathy and with the various clinically differentiated illnesses herein referred to. To be sure other organisms—staphylococci, diplococci, melitensis, etc.—are named even in conditions not specifically defined as a clinical disease such as typhoid fever, etc., but the predominating organism is the streptococcus. I am more and more impressed by the frequency with which causal agents of disease attack and enter the body through the upper end of the alimentary canal—oronasopharynx. There is a good deal of evidence

that the association of infection at the beginning of the alimentary canal—oropharyngeal cavity—with the abdominal manifestations centering in the general region of the terminal ileum is no mere coincidence. Corroboration of this is obtained in both experimental work (Poynton and Payne, and Adrian), and in clinical practice. Similarly, in the literature, reference has been made to the connection between appendicitis and an original oropharyngeal infection. I am also struck with the importance of an allergic mechanism in many of the previously mentioned conditions in which abdominal lymphadenopathy occurs. The rapid and abundant distribution of an exanthematic rash is probably based on an allergic distribution. In the visceral crises the edematous areas in the intestinal tract show remarkable similarities to external forms of angioneurotic edema and are undoubtedly indicative of a similar mechanism. Various forms of purpura commonly accompany the visceral crises. In the hyperacute fatal form of purpura there is indication of an overpowering biological mechanism, and no other branch of medicine comes so quickly to one's mind as that pertaining to allergic phenomena. Most probably the allergic antigen in any case is a bacterial product. Some of the phenomena remind one of histamine poisoning and histamine-like bodies are found commonly in the intestinal tract

3 The great facility with which generalized or mesenteric lymphadenopathies are associated with many apparently widely differing diseases indicates the great tendency for lymphatic absorption of these diseases during this period of life. It is practically impossible to obtain an accurate visualization of the general and ordinary condition of the enormous surface extent of the mucous membrane of the intestinal tract especially of the jejunum-ileum. It seems highly probable, nevertheless, that more frequently than one ordinarily imagines, there is some inflammation of this membrane, i.e., enteritis. There is every reason to believe that such inflammation can be responsible for many hitherto not sufficiently explained abdominal symptomatology, acute and chronic upsets in digestion, cyclic vomiting, etc., which are now thought to be "functional" in origin for many cases of diarrhea for which, at present, no adequate cause can be found, and for some other transient disturbances in the functions of the stomach and bowel, which so commonly accompany "colds" or "throat infections" or other generalized infections. Accurate correlation and integration of these symptomatology with the little and infrequently available knowledge obtained during postmortem examination is difficult. Com-

mon bacteriological causes for such transient and often unrecognized forms of enteritis may be the organisms or their toxins of the dysentery, enteritides, and colon groups of bacteria as well as staphylococci and streptococci. The studies of Childrey, Alvarez and Mann indicate that the digestive upsets that follow the eating of too much food or of undigestible food may well be due to injury wrought in this way to the absorptive power of the mucous membrane of the small bowel.

4. Intra-abdominal lymphadenopathy occurs under several basic conditions: (a) as an accompaniment or integral part of some definite disease such as typhoid fever, dysentery, etc., (b) as a secondary manifestation to some intestinal lesion of more or less obscure origin such as nonspecific granuloma of the intestine, (c) as an incompletely understood accompaniment of indefinite groups of diseases usually associated with streptococci of one or another strain—the rheumatic group, for instance, (d) as a lymphadenopathy without any demonstrable or discoverable preceding causal lesion either nearby or at a distance that is, non-specific mesenteric adenitis.

5. The dominating position of the isolated and aggregated collections of lymphadenoid tissue at those points of the alimentary canal—oronasopharynx—where physiological activity and stress is normally at a maximum, where bacterial attack is most apt to occur, where the products of bacterial attack and invasion are therefore most commonly developed and absorbed, neutralized without perceptible evidence or counteracted, blocked, and destroyed in the appropriate associated lymph nodes in the manifestations of disease. In intra-abdominal lymphadenopathy this corresponds to nonspecific mesenteric adenitis.

6. The great similarity in anatomy, physiology, etiology, mechanism and pathology between such forms of disease originating in the oronasopharynx and that originating in the lower ileum in either case lead to nonspecific forms of lymphadenopathy. This fact must be emphasized in order to wipe away any question of obscurity with which nonspecific mesenteric adenitis has been surrounded.

7. The similarity of the anatomical changes in the mesenteric nodes of the nonspecific type and those in the lymphadenopathies which occur in the other collateral or specific groups of diseases are reviewed herein.

8. In the great majority of the cases of nonspecific mesenteric adenitis it is not possible to prove any definite tuberculous etiology nor do the clinical facts give any reason for suspecting or

believing that the great majority of these conditions are tuberculous.

One must get away from the idea that mesenteric adenitis is some isolated bizarre peculiar or obscure disease. Rather one must understand that it has its counterparts in other lymphatic regional areas, that it is a sequel of other disease and infections, that it is a constant secondary phenomenon in many acute and chronic, mild and severe diseases of the intestinal tract, and that no one etiological factor or cause is responsible for the condition. This is not only my own opinion but has been pointed out also by Strombeck.

Inasmuch as in many cases abdominal lymphadenopathy is part and parcel of some larger definite clinical entity treatment must follow along the lines known by experience to be correct and adequate for the original disease. In nonspecific mesenteric adenitis and in the absence of any suppuration or other complication, none but conservative treatment would be indicated if one could so perfectly diagnose the condition that the fear of an undiscovered acute appendicitis or other surgical emergency could be definitely eliminated. Unfortunately this is not possible at the present writing in clinical practice, and abdominal explorations are more or less frequently necessary in order to establish the true nature of the intra-abdominal condition.

THE RÔLE OF CONSERVATIVE PROCEDURES IN TREATMENT OF SURGICAL EMERGENCIES

IT is of the utmost importance for the surgeon called on to perform emergency operations to realize that with each patient he faces two distinct major problems first, the saving of a life and, second, the correction of a pathological condition. Naturally their respective importance is in the order named, but because of zeal to effect a cure, it is sometimes easy to overlook the immediate problem at hand namely the preservation of life. For the latter often a temporary or palliative type of emergency operation will be sufficient to correct the physiological disturbance. After the patient's condition improves, radical corrective procedures can be undertaken with reasonable safety. The problem in emergency operations is entirely different from that presented by the patient with a more or less chronic ailment amenable to surgical treatment who being otherwise in good condition and electrolyte balance can be sub-

jected safely to the needed corrective operation usually at one stage.

Before any emergency operation likewise two other important problems should be solved. If the surgeon is to give the patient the entire benefit of present knowledge and meet successfully the major problem that of preservation of life. These are first, an accurate pre-operative diagnosis and second, adequate pre-operative preparation. The diagnosis, surgical abdomen was often justifiable forty years ago but is permissible today only occasionally with the laboratory procedures, and stored blood and plasma which are now available to the surgeon. A few years ago the surgeon was forced to operate on patients in shock because intravenous infusions, blood and plasma were not available but with these agents at hand the patient's condition can be improved before operation and during these extra minutes or hours, as the case may be, an accurate diagnosis can be made. Certainly a patient who has pneumonia or coronary thrombosis is never improved by exploratory laparotomy and without a careful accurate diagnosis each can be mistaken readily at times for a "surgical abdomen." Likewise intravenous fluids in the quantity used in combating shock would only add to the gravity of the situation if administered to a patient following an acute coronary accident.

The value of intravenous fluids in cases of intestinal obstruction has been appreciated for almost two decades. It is not generally known, however that children and infants are especially vulnerable when subjected to surgical procedures when their fluid balance is poor. Also any patient who gives a history of vomiting or ileus should not receive an

anesthetic until a stomach tube has been passed and the stomach emptied of its contents

If all problems in emergency treatment were as direct as that of early uncomplicated acute appendicitis in which both the problems of urgency and cure are settled, there would be no excuse for this dissertation. Fortunately, the same is true in the majority of cases of acute cholecystitis, perforated peptic ulcer, strangulated hernia, ectopic pregnancy, and twisted or bleeding ovarian cyst. Because of the relative good condition of the patient, who has one of these lesions, life may be preserved and a cure effected at one operation. Unfortunately, some patients present a graver problem because of their poor condition, or the nature of their affliction, and a conservative procedure only must be performed that may or may not also result in cure of the pathological condition. This probably was first appreciated in the management of acute obstruction of the large bowel and it is now the accepted procedure, if the obstruction does not subside in a few hours after institution of conservative measures, to perform cecostomy or colostomy and to defer removal of the obstructing lesion until the obstruction is entirely relieved. This course allows time for evacuation and cleansing of the bowel, which is so important in the preparation for operations on the colon. Likewise, when an infant, an aged patient, or a patient in poor condition has a strangulated intussusception of the intestine, volvulus, or hernia, an exteriorization operation with proximal enterostomy as an emergency procedure gives a much greater hope of recovery than resection and a primary anastomosis. The intestinal continuity can be re-established with considerably less risk a few days later when the emergency is over. The fact that the intestinal obstruction is the item of first importance should be remembered in dealing

with strangulated hernia and not the herniorrhaphy

Any more radical procedure than simple closure of an acutely perforated peptic ulcer doubles the mortality rate. Since 80 per cent of patients remain well after this conservative procedure and usually medical regimen has not been tried, there seems to be little excuse for subjecting a patient in shock to gastroenterostomy or gastric resection. The effectiveness of medical regimen, which may be used to prevent further operation, is portrayed by patients with chronic duodenal ulcer. In these cases medical regimen almost invariably is advised and operation is required for relief in only about 15 per cent. In operating on the acutely inflamed gall bladder, the experienced surgeon will be able to accomplish cholecystectomy without difficulty in most instances. Occasionally, however, its removal will be hazardous because of the extent of the inflammation present or the poor condition of the patient. In such cases cholecystostomy can be performed unhesitatingly with the assurance that 85 per cent of such patients will not require cholecystectomy later. The management of perforation of the appendix with peritonitis is a controversial subject, but most surgeons who pursue an operative or radical policy become very conservative as soon as the peritoneal cavity is entered. Frequently, only drainage is instituted unless the appendix is free and readily accessible and the patient's condition warrants its removal. Great care is taken to prevent the breaking up of protecting or walling off adhesions. If a localized abscess shows no signs of resorption, it is drained, and if appendectomy is not accomplished at the primary operation its removal is recommended in the interval.

The gross mortality rate with emergent abdominal surgical procedures in experienced

hands is in the neighborhood of 10 per cent. The employment of preliminary conservative procedures in certain complicated problems could lower this figure appreciably.

JOHN M. WAUGH

ADVANCES OF ABDOMINAL SURGERY IN INFANCY

THERE is probably no field of surgery that has been overlooked so much as that pertaining to infants and children. In fact, it is only within the past 5 to 10 years that any appreciable proportion of the medical profession has realized that the infant and child are subject to almost all the pathological conditions found in adult life plus many conditions never seen in the older age group. This change in point of view is strikingly evidenced by the great increase in the number of articles on children's surgery appearing in the leading medical journals and by the tremendous increase in the demand by young men for training in this field of surgery. Of course, with this increased interest in a particular phase of surgery there has been a marked improvement in the results obtained.

This improvement has been especially striking in the abdominal surgery of infants. It is interesting to recall that although congenital pyloric stenosis was well described by Beardsley as early as 1787 little or no attention was paid to the condition for well over a hundred years. Untold hundreds of infants must have died of this condition in the years intervening between then and the present day. In fact even in the very recent past the mortality remained over 50 per cent but today in well organized children's surgical clinics the mortality has dropped to a fraction of 1 per cent. This desirable change has come about by earlier recognition of the condition with an earlier diagnosis, by better preoperative prepara-

tion of the patient, by improved operative technique and by more intelligent postoperative care.

In 1916 Holmes made a careful examination of 120 pathological specimens of atresia of the bile ducts which showed that an appreciable number of these patients had ducts available for anastomosis to the bowel for any surgeon who wished to make the attempt. Yet it was not until 1927 that the first successful anastomosis of a congenital atresia of the bile ducts was performed. Since this first successful operation was performed at The Children's Hospital of Boston 6 other cases of atresia of the extrahepatic bile ducts have been successfully operated on and more than this number of cases of stenosis of the ducts have been relieved by surgical means. The relief in both groups has been permanent. It appears that over 20 per cent of the cases of congenital obstruction of the bile ducts are amenable to surgical relief and that in this group the operative mortality is not unduly high. It is surprising that there are not more successful results reported in the current literature.

Until very recent years the cure of a patient suffering from congenital atresia of the intestine was regarded as a surgical curiosity but reports of successful results are becoming much more common. Were it more generally appreciated that any infant who starts vomiting on the first day of life and continues to do so may be suffering from this condition, and were it also appreciated that the diagnosis can be simply and accurately made in the vast majority of instances, the successes would increase even more rapidly. A single x ray plate without the use of contrast media will not only suggest the diagnosis of intestinal obstruction but will often indicate the approximate site of the obstruction. The optimum time for performing these difficult anastomoses is within the first 48 hours of life. At this age infants

stand major surgical procedures extremely well. The mechanical difficulty of excessive distention has probably not taken place and gangrene of the bowel with perforation and peritonitis has not developed. It is still all too common for such infants not to be referred to the surgical clinic until they are *in extremis*. Of course, it must be recognized that special surgical technique is required for such cases, but this has already been developed in several clinics and should be developed in many more in the near future.

The intestinal obstruction due to faults of rotation, though often not complete and therefore not quite so urgent as the atresias, still present serious problems of early life. With our present knowledge of these conditions and the methods of surgical approach they can be effectively and permanently relieved in most instances.

In 1931 Hedblom showed that 75 per cent of infants having diaphragmatic hernia died before the end of the first month of life, and the mortality would be higher if the hernia through the esophageal opening had been excluded. If in newborn infants presenting symptoms of cyanosis, circulatory difficulty, or vomiting, the possibility of diaphragmatic hernia were more commonly considered, many fatalities from this condition could be avoided. Here again, as with the atresias of the bowel,

an x-ray examination without the use of contrast media will usually give an accurate diagnosis. When a diagnosis has been made of diaphragmatic hernia of major degree in the newborn infant, operation should be resorted to without delay. The policy of delay has yielded a mortality of over 75 per cent in the first month of life, whereas recognizing that the optimum time for surgical intervention is in the first 48 hours of life has reduced it tremendously. In the first two days of life the distention has not become marked and there is a better chance of being able to replace the abdominal viscera within the peritoneal cavity without undue pressure. When the tension of closing the abdominal wall is too great, a two stage closure has been proved to be a life-saving procedure. If this present plan of procedure is followed, it should be possible to reduce the present high mortality by 50 per cent or more.

These are but a few examples of the marked recent changes and advances in the field of abdominal surgery of infants. The knowledge of the pathological conditions which exist at this age, the development of suitable surgical technique, and the correct postoperative care of those small patients have also produced similar improvements in surgical conditions involving other parts of the body in newborn infants.

G G G The veins and arteries distributed into the Spleen.

Fig

Reproduced from Vesling Anatomy

The Sweet-bread (Pancreas) Glandular part of the *Albugo*, very profitable for consuming and purging the Chyle, and preparing it for the Liver and Spleen before be turned into blood, for in Nature's design each the blood is full, which either for nourishment of the first, the second, or to make the food for the Glandular part of it, by divers degrees it flows, even to the liver back turns into blood, short in the stomach, connects in the stomach, which is of consequence by the flow of, and by the force of the Sweet-bread, from the liver and the stomach, and therefore the Sweet-bread is the last full of Chyle as you may find it very difficult, creating above, and out each back.

Also there small oblong and angular channel in the Sweet-bread, lately found out by our Physicians, such as various experiments the Reticulum and flow of vein. It is thick from the Gut called Duodenum, Extremity in the extremity of the lateral pore, having common Orifice with an outward flow, continues near the lateral pore, forms distinct places, directed contrarily in the Sweet-bread with flow, yet very many branches; wide at the beginning, and continues by degrees before comes at the extremity of the Sweet-bread. Substance is double in size, but unequal in length, and which near the lateral pore at base. Spleen's broad distance.

The use of this channel is so vast hard to be found out, for finding it brings certain Spleen pores not unlike to the Gall, it separates the juice of several Matters from the Chyle and carries away to the Gut Duodenum, and therefore that being stopped, the Sweet-bread feeds by means of the extremities retained, and is, mostly vessels being by this means unimpeded the Liver and Spleen receive no small damage.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE book *Bacillary and Rickettsial Infections* by William H. Holmes¹ should have a wide appeal to those physicians and medical students who have a scholarly interest in disease. This volume takes up the large group of infectious diseases caused by bacilli and by rickettsia, namely the enteric infections, diphtheria, tetanus, gas gangrene, botulism, adulant fever, tularemia, plague, brucellosis, typhus, spotted fever, and a number of less important infections. The picture of each disease is presented against a rich historical background which gives the reader a sense of perspective. The development of our knowledge concerning the disease and its effect on human history are sketched in vivid terms. Consequently when the symptomatology and laboratory findings are discussed, one gets a splendid conception of the disease as a historical, clinical, and scientific entity. Dr Holmes' style is eminently readable, his arrangement of material with comments in small type along the margin a useful one, and the profession owes him a debt of gratitude for introducing both scholarship and good literary style into sound medical writing.

The book was written as a textbook. The essential facts about the etiology, pathology and symptomatology of these infections are clearly presented, but these sections are not comprehensive enough to make the volume a useful reference work. Bacteriologists may well be disappointed by the small space devoted to bacteriology and immunology. Clinicians may feel that insufficient emphasis is placed upon differential diagnosis and treatment. If never the author did not set out to write a reference book, but rather an introduction to the study of medicine, or an "orientation in medicine" as the publisher describes it. In this he has succeeded admirably. For the second year student in bacteriology Dr Holmes' book will give meaning to his long hours of laboratory work. If students in the third and fourth years take up the study of the infectious diseases with this book, they will gain a insight which can never come from mere study of the ordinary textbook. Later in their careers they may wish to consult the larger systems for information on specific points, but this volume will give them admirable understanding of the disease as a whole. Older physicians will find fascinating reading in these chapters, which will not only refresh and supplement their medical knowledge, but also kindle some of the enthusiasm of their student days.

Perhaps Dr Holmes should be commended most highly for the broad outlook on medical problem which he has skillfully woven into the text of his work. In the chapters on tuberculosis particularly, he has shown how closely the disease is interlarded with the social and economic problems of our society. This book sets the infectious diseases in their proper perspective in the field of medicine and human relations, and every medical student who aspires to be more than a mere craftsman should study this volume during the course of his training.

CHARLES A. J. KWA

Since this review was received, Dr Holmes passed away on November 3, 1940.

THE small textbook, *Practical Dermatology and Syphilis* by Robinson, is compact and intended primarily for the medical student. It is a synopsis of most of the common skin diseases found in the average standard textbook of dermatology. Its purpose, perhaps, is much the same as that of the *Synopsis of Medicine* by Henry L. Tidy, namely to assist those who wish to review rapidly their knowledge of dermatology.

The general arrangement of the book follows that of the larger more comprehensive textbooks on the subject, and while the subject matter is very briefly handled, in most cases the descriptions are adequate.

There are 430 photographs, but they are reduced so much in size that they fail to serve their purpose that of giving the student an adequate picture of the disease. Then, too, they show many defects in lighting, depth, and sharpness of focus.

The book can only be recommended to beginners in dermatology as a primer, with emphasis on the warning of the author that for more comprehensive study and reference more extensive textbook should be consulted.

EDWARD A. OLIVER.

THE thoracic monograph, *Lipid Metabolism of the Cellular Lipid Metabolism* originally written as a section of *Oxford Lecture Notes in Medicine* includes studies on lipid metabolism begun 30 years ago by the author and his associates. The subject is presented in five parts: physiology and chemistry, hyperlipemia, xanthomatosis, Gaucher's disease, and Niemann-Pick disease. Clinical examples of the various conditions described are numerous and the

role of alcohol is emphasized in explaining the recent increase in the number of cases of pellagra in cities.

In the foreword Dr. E. A. McCollum makes the following statement: "Nowhere else is so complete a history of investigations relating to pellagra, and the assembled quotations and comments make a fascinating story. Clinicians will be entertained and instructed by reading the views of their tedious col-

league, which point out how as the result of primary deficiencies, bodily conditions may through debility and derangement of function of the gastro-intestinal tract and the liver become unable to utilize indispensable nutrients in an adequate dietary. The book is a distinct contribution in that it extends the deficiency disease viewpoints beyond simple chemical reasoning into the field of perverted physiological function."
HOWARD B. CARROLL.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

CORRESPONDENCE

FAT EMBOLISM, A CLINICAL AND EXPERIMENTAL STUDY

To The Editor: In my article entitled "Fat Embolism: A Clinical and Experimental Study," published in the April 1911 issue of this journal, I stated on page 74:

"Decolin sodium (sodium dehydrocholate) has been recommended by Paul deLaen Chemical Company as a therapeutic agent in the treatment of fat embolism."

This statement should be read that Mr. Paul deLaen, president of Riedel & Haen Inc., manufactures

the form of decolin sodium, called my attention to the report by D. E. Rappert on November 7, 1910, and suggested that D. Rappert's work on fat embolism merited confirmation by further investigation.

I regret that my statement indicated that M. deLaen recommended decolin sodium as a therapeutic agent in the treatment of fat embolism. This was an error because, in M. deLaen's opinion, the available data are insufficient to justify its use in the treatment of this condition at the present time. I did not want to misquote a corporation of such splendid reputation.

Committee on Arrangements

LELAND S MCKITTRICK, *Chairman*, RICHARD H SWEET, *Secretary*

PRELIMINARY PROGRAM FOR 1941 CLINICAL CONGRESS

THE thirty-first annual Clinical Congress of the American College of Surgeons will be held in Boston November 3 to 7, when the fellows of this great medical center will sponsor a program of operative clinics and demonstrations covering all phases of surgical activity. The Congress has been held in Boston on several previous occasions, the first in 1915 and last in 1934. These meetings have made notable contributions to surgical and medical knowledge. Those who will attend in 1941 may anticipate a program of broad scope and interest, for the surgeons and clinicians of Boston have complete facilities at their command in the three medical schools and the thirty or more approved hospitals which will participate.

CLINICAL PROGRAM

Under the leadership of a strong and representative Committee on Arrangements, plans are already under way for a complete and varied program for the five-day meeting. An extensive schedule of clinics and demonstrations is being arranged in the hospitals and medical schools which will, as usual, be the major feature of the Clinical Congress. Visiting surgeons will have every opportunity to obtain first hand information on a wide variety of surgical and related subjects as presented in the environment of excellent hospital facilities. In the operative clinics, surgical technique, use of operating room equipment, and organization of personnel will be demonstrated. Symposia and non-operative clinics will deal with the broader and equally important aspects of diagnosis, related non-surgical treatment, pre-operative preparation, and postoperative care, presented by means of discussion and through the demonstration of a wide variety of clinical material. Hospital diagnostic depart-

COMMITTEE ON ARRANGEMENTS

Leland S McKittrick	William E Ladd
Chairman	Frank H Lahey
Richard H Sweet	Donald Munro
Secretary	Charles G Mixer
Arthur W Allen	Frank R Ober
Edward D Churchill	Robert B Osgood
Howard M Clute	George L Tobey, Jr
E Granville Crabtree	Frederick H Verhoeff
Elliott C Cutler	Irving J Walker
Frederick C Irving	Shields Warren

ments will offer important contributions in their respective fields. Specialists in varied fields, as well as surgeons, will participate in the discussions, so that many subjects will receive consideration from different viewpoints.

The medical schools and their affiliated hospitals have expressed a willingness to plan a series of exhibits demonstrating their work in clinical investigation and the latest advances in surgical research. These exhibits will be available for study in the local hospitals during the entire meeting. The basic science departments of the medical schools will present important work related to surgical practice. Thus, the Boston institutions will have much to offer in the way of a highly concentrated practical postgraduate course in surgery and allied subjects. A preliminary clinical program appears in the following pages. The preliminary clinical program as published at this time is incomplete in that a number of hospitals that will participate in the clinical program are not included. Schedules for the following hospitals will appear when the clinical program is again published: Lakeville State Sanatorium, New England Hospital for Women and Children, Newton, and St. Elizabeth's.

The program of each hospital is arranged to cover subjects in general surgery, obstetrics and gynecology, fractures, orthopedic surgery, thoracic

surgery, neurosurgery, genito-urinary surgery, ophthalmology and otolaryngology. Thus the visiting surgeon may select the clinics which he wishes to attend. Presentation of subjects under these classifications will be so correlated that he will have the opportunity to devote his time continuously to clinics dealing with the specialty in which he is most interested. The daily clinical bulletin will present the program according to the above classification. The complete detailed clinical program for the succeeding day will be posted each afternoon in the form of bulletins at headquarters in the Statler Hotel and distributed in printed form each morning. The preliminary programs and the general program to be published later will include as much detailed information as it is possible to present in advance, but it will be necessary for those who attend the Congress to make their clinic ticket selections from the daily bulletins.

SCIENTIFIC SESSIONS

The opening scientific session of the Clinical Congress, the combined presidential meeting and convocation, will be held on Monday evening in Symphony Hall. At this session the new officers of the College will be inaugurated and the initiates received into fellowship. Dr. Everts A. Graham, of St. Louis, will deliver the presidential address.

Eminent surgeons and specialists, recognized as authorities in their fields, will address the scientific meetings which will be held on Tuesday, Wednesday and Thursday evenings in the ballroom of the Copley Plaza Hotel. Special scientific meetings are being arranged for those who are interested in ophthalmology and otolaryngology on Tuesday, Wednesday and Thursday evenings. The Board of Regents of the College is giving careful attention to the selection of the speakers and subjects for these evening sessions, so that a well rounded program introducing the newest developments in general and special fields may be assured.

During recent years, at both the Clinical Congress and sectional meetings of the College, panel discussions held at the headquarters hotel have created unusual interest. Therefore, a schedule of thirty or more of these sessions is being planned for Monday, Tuesday, Wednesday and Thursday afternoons. These panels will be led by recognized authorities in each field who will have the aid of collaborators equally qualified to present fundamental facts on the chosen subject, and to direct the discussion in such a way that various viewpoints may be expressed. These sessions afford an opportunity for a large number of surgeons to participate and learn of the discoveries and experiences of others. The general plan

is for a ten-minute presentation of the subject by the leader, collaborators to follow with brief discussions on different phases of the topic, following which general discussion from the floor will be the final and major feature of each session.

Because of the widespread interest in the special subjects, a symposium on fractures and other traumas is being planned for one afternoon, and a symposium on cancer for another afternoon. As in former years, these sessions are expected to attract a large attendance.

A new feature introduced at the Clinical Congress in Chicago and which proved popular is again being planned for Friday afternoon. For these conferences ten special fields have been selected, and a pertinent subject of current interest will be briefly presented by a leader at each session. Discussion from the floor is directed by the leader and any surgeon attending is privileged to present a special problem related to the field under discussion with which he is concerned. Such opportunity for large groups of surgeons to participate in a consultation conference of this nature is apparently welcome.

The Board of Regents and the local committee aim to provide a varied type of program that will enable each individual surgeon to learn of the newer developments in many fields. The interests of both the general surgeon and the surgical specialists are being carefully considered in arranging all features of the program.

SPECIAL MEETING OF BOSTON SURGICAL SOCIETY

The Boston Surgical Society will hold a special meeting on the evening of Friday, November 7, in the ballroom of the Copley Plaza Hotel, to which all fellows of the College and other surgeons attending the Clinical Congress are invited to be present. The occasion of this special meeting of the society is the presentation of the Bigelow Medal to Dr. Allen O. Whipple, of New York, for his outstanding contributions to the advancement of surgery.

MEDICAL MOTION PICTURES

The visual education aspects of the program of the Clinical Congress will again be enlarged with the aid of medical motion picture films. The latest available pictures showing surgical procedures and related subjects will be exhibited. The schedule will be arranged so as not to conflict with either the clinical program at the hospitals or the scientific sessions, and will include both sound and silent, standard and color films which have been approved by the Committee on Medical Motion Pictures.

HOSPITAL CONFERENCES

On Monday morning at 10 o'clock, in the Ballroom of the Copley-Plaza Hotel, the first session of the twenty-fourth annual Hospital Standardization Conference will open the Clinical Congress. At this session the 1941 list of approved hospitals, cancer clinics, and hospitals approved for graduate training in surgery and the surgical specialties will be officially announced. Dr. Evarts A. Graham, of St. Louis, president of the College, will preside. The hospital conference will continue on Monday afternoon in the same room, with sessions on Tuesday, Wednesday, and Thursday mornings, afternoons, and evenings. Programs are being arranged to interest hospital administrators, heads of various hospital departments and their personnel, nursing groups, and members of governing boards. One hospital conference in particular will be devoted exclusively to subjects of vital interest to members of governing boards. All aspects of the public relations problem will be discussed.

At a joint session with the Association of Record Librarians of North America, medical records will receive special consideration. National organizations representing various groups of hospital personnel will co-operate and participate in these meetings.

Some of the hospital conferences at the headquarters hotel will be formal sessions, others will be in the nature of panel discussions, round table conferences, and open forums. In certain sessions there will be a presentation of specific phases on a general theme by several speakers, in others a variety of subjects will be covered. The program will be developed to meet current needs, and from all indications is likely to emphasize from all angles the rôle of the hospital in the program of national defense.

As a special feature of the hospital conference it is planned to develop a program that will definitely appeal to the general surgeons and surgical specialists. This will take the form of a large general meeting with a series of panel discussions on appropriate subjects dealing with the care of patients, educational functions of the hospital, the control of surgery, and the clinical work in the related specialties. Organizations representing the specialty groups will be invited to participate in this phase of the program. Special consideration will be given in this series of meetings to the important subject of graduate training in general surgery and the surgical specialties. It is hoped that through this means the fellows of the College may become better acquainted with its extensive program of hospital activities which is

aimed at improvement in the environment in which the surgeon is working.

PUBLICATION OF PROCEEDINGS

As in former years, the formal papers which are presented at the scientific sessions of the Congress will be presented in a special issue of the official journal of the College, *SURGERY, GYNECOLOGY, AND OBSTETRICS*, published in February following the meeting. This issue is furnished without additional charge to all fellows, junior candidates, and others who register for the Congress as invited guests. The papers which are presented in connection with the hospital standardization conference are published in subsequent issues of the *Bulletin* of the American College of Surgeons.

ADVANCE REGISTRATION

The hospitals and medical schools of the Boston area afford accommodations for a large number of visiting surgeons, but to insure against overcrowding, attendance at the Congress will be limited to the number that can be comfortably accommodated at the clinics. The limit of attendance will be based on a survey determining the available facilities in the participating hospitals and schools. It is expected, therefore, that surgeons who wish to attend the Congress will register in advance. A registration fee will be required in order to provide funds with which to meet expenses of the meeting. A formal receipt will be issued to each surgeon registering in advance, which will be exchanged for a general admission card upon presentation at headquarters during the Congress. This card, which is not transferable, must accompany all requests for clinic tickets and be presented for admission to the scientific sessions.

A resolution adopted by the Board of Regents provides that the registration fee for fellows of the College and endorsed junior candidates shall be \$5.00, that no fee for the 1941 Clinical Congress shall be required of initiates (class of 1941), that the fee for surgeons who are not fellows, attending as invited guests of the College, shall be \$10.00.

As in previous years, admission to clinics and demonstrations in the hospitals and certain of the scientific meetings at headquarters will be controlled by means of tickets. This plan provides for the distribution of visiting surgeons at the various clinics and other meetings, and helps to insure against overcrowding. The number of tickets issued for any clinic will be limited to the capacity of the room in which the clinic is held. Visiting surgeons are urged to co-operate in making the clinic ticket plan a success.

HEADQUARTERS AND TECHNICAL EXHIBITION

Headquarters for the Congress will be established at the Statler and Copley Plaza Hotels where there are ample facilities for accommodating the Congress. All of the public rooms have been reserved for the exclusive use by the College during the five-day meeting. Registration for visiting surgeons and their ladies, the Technical Exhibition, executive offices of the College and certain scientific sessions and medical motion picture exhibitions will be located in the Statler Hotel. Registration for those attending the hospital conference, exhibits of College activities, and the morning, afternoon and evening hospital conferences will be located in the Copley Plaza Hotel. The evening scientific sessions on Tuesday, Wednesday and Thursday will also be held at the Copley Plaza.

The Technical Exhibition, registration desk for attending surgeons, clinic ticket and information bureau will be located in the ballroom on the mezzanine floor of the Statler Hotel. Additional space for the exhibition will be provided in the Assembly Room and the mezzanine lounge adjacent to the ballroom. Leading manufacturers of surgical instruments and supplies, sutures, dressings, pharmaceuticals, operating room equipment, x-ray apparatus, hospital equipment of all kinds, and publishers of medical books will be represented in the exhibition. It will provide for the

visiting surgeons and hospital people an opportunity of carefully inspecting the finest modern products of all those industries which are helping to improve the service of hospitals and surgeons.

BOSTON HOTELS AND THEIR RATES

In addition to the headquarters hotels, the Statler and Copley Plaza, there are a number of first-class hotels within a short distance of headquarters. These will provide ample facilities at reasonable rates. It is suggested that reservations for hotel accommodations be made well in advance of the meeting. The following hotels are recommended by the Committee

	Minimum Rates with Bath	
	Single	Double
Bellvue, Beacon Street.	\$1.00	\$1.50
Bradford, 75 Tremont Street.	1.00	1.50
Brunswick, 530 Boylston Street.	1.00	1.00
Buckminster, 645 Beacon Street.	.90	1.00
Copley Plaza, 38 St. James Avenue.	4.00	6.00
Copley Square, 47 Huntington Avenue.	.75	1.00
Kenmore, 400 Commonwealth Avenue.	1.50	1.00
Lenox, Exeter Street.	1.00	1.50
Lincolnshire, 30 Charles Street.	1.00	1.00
Parker House, 60 School Street.	1.50	1.00

 BENJAMIN RISEMAN Gumma of nasopharynx and lung
 SAMUEL W. GARFIN Treatment of fractures of the jaw
 PHILIP E. A. SHERIDAN, CHARLES DEWOLFE, and FREDERICK HEDMLICK Presentation of cases

Wednesday

GENERAL SURGERY

Staff—9 Dry clinic

- Department of Pathology Splenogenic myeloid metaplasia, argentophil tumors (carcinoid)
 DR JOLIFF Surgical treatment of myeloma
 F W O'BRIEN Cancer and x ray therapy
 E A COONEY Carcinoma of breast.
 A R KIMPTON Cancer of large intestine
 CHARLES LUND Cancer of mouth
 I C WALKER Cancer of stomach
 Staff—2 Symposium Thyroid disease
 R C COCHRANE Tumors of parathyroid with lantern slides
 D D BERLIN Hyperthyroidism with cancer of thyroid
 W T SALTER Graves' disease without hypertension
 RICHARD SMITH Adenoma of thyroid
 R C COCHRANE Complication of thyroidectomy

Staff—2 Symposium Vitamins in surgery

- CHARLES LUND and J H CRANDON Vitamin C and wound healing
 WALTER WEGNER and MERRILL MOORE Vitamins in presence of head injuries
 DR MIKELJOHN Presentation of cases

Staff—2 Symposium

- GORDON M MORRISON Radial nerve injury with fracture of humerus
 J E FLYNN Anatomical and clinical investigations of deep fascial space abscess of the hand
 T K RICHARDS Traumatic injuries of the knee joint
 J E FLYNN Dupuytren's contracture
 A P AITKEN Epiphyseal separation
 J E FLYNN Treatment of traumatic lesions of the hand
 ROBERT ULIN Club feet

OBSTETRICS AND GYNECOLOGY

Staff—9 Dry clinic

- Speaker to be announced Anesthesia and analgesia with special reference to spinal and intravenous anesthesia
 DR REGINALD and R D MARGESON Placenta previa in patients previously delivered by low transverse cesarean section
 FREDERICK L GOOD Physiology of lower uterine segment
 DANIEL J MCSWEENEY Radiographic pelvimetry
 Staff—9 Dry clinic
 F W O'BRIEN Results in treatment of carcinoma of the uterus in the tumor clinic of a general hospital
 FREDERICK PARKER, JR and JOHN T WILLIAMS Pathology of so-called fibrosis of the uterus

Thursday

GENERAL SURGERY

OTTO J HERMANN and associates—9 Symposium Low back pain

- OTTO J HERMANN Introduction
 JOHN T WILLIAMS Gynecological aspects
 AUGUSTUS RILEY Genito-urinary aspects
 ROBERT ULIN A rational method of routine back examination based on anatomical and physiological factors
 JOSEPH SHORTELL Low back pain with negative x ray,

- RICHARD H. WALLACE—30. Acute cholecystitis
 JOHN D. STEWART—30. Obstructive jaundice, II or
 I incision, preparation of the patient, and after-care.
 RICHARD H. WARREN—315. Carcinoma of the gall
 bladder
 Staff—330. Operations Extra-hepatic biliary tract
 L. S. McKEITHEN and associates—2. Symposium. Peri-
 pheral vascular disease.
 L. S. McKEITHEN—2. Fundamental considerations,
 classification, differential diagnosis
 EDWARD HAMILTON, JR.—5. Thrombo-angiitis obli-
 crata. Outline of treatment, nerve crushing, mechan-
 ical aids, indications for amputation.
 H. E. KIRKLAND—35. End-result study with particular
 reference to the economic aspect of the disease.
 RICHARD H. WARREN—35. Arterio-sclerotic gangrene
 with and without diabetes. Indications for and tech-
 niques of minor amputation.
 T. C. FRITZ—130. Indications for and technique of
 supracondylar amputation.
 R. H. SMITHWICK—330. Lumbar sympathectomy, its
 role in the treatment of obliterative disease indica-
 tions for operation and operative technique
 Staff—4. Operations. Supracondylar amputation for
 gangrene, nerve crushing for relief of pain, lumbar
 sympathectomy

GENITO-URINARY SURGERY

- G. G. SMITH and associates—9. Operative and dry clinic
 Staff—9. Operations.
 F. H. COLBY—30. Genito-urinary tuberculosis
 RICHARD CRUTE—50. Results of treatment with
 estrogenic substances in prostatic hypertrophy
 S. B. KIELLEY—Complications of transurethral
 resection.
 LORESTER WOODRUFF—40. The female urethra
 G. G. SMITH and associates—2. Operative and dry clinic
 Staff—2. Operations
 G. G. SMITH—330. Treatment of prostatic cancer
 ARTHUR WILLIAMS—350. Chronic prostatitis
 W. F. LEUBENETTER—470. Renal arteriography
 JOSEF P. GIER—490. The male hormone

THORACIC SURGERY

- E. D. CRITCHFIELD and associates—9. Symposium. Pri-
 mary tumors of the lung and mediastinum

Thursday

GENERAL SURGERY

- A. W. ALLEN and associates—8. Symposium. Duodenal
 ulcer
 C. M. JONES and associates—8. Medical considerations
 A. O. HANSTON and associates—830. Roentgenological
 diagnosis.
 E. B. BENDER—830. Gastroscopy gastritis
 A. W. ALLEN—930. Surgical considerations
 HOWARD UHLINGER—940. Acute perforation
 C. E. WELCH—Malfunction of anastomotic stoma
 and after-care.
 Staff—30. Operations.
 V. H. KARAKUL—8—30. Operative and dry clinic
 Plastic surgery presentation of cases operated upon for
 various deformities
 L. S. McKEITHEN and associates—Operative and dry
 clinic. Acute small bowel obstruction
 RICHARD H. WARREN—Physiological aspects of non-
 strangulation obstruction, cause of death
 L. S. McKEITHEN—30. Factors influencing mortality
 rate

- S. P. SARRIS—40. Diagnosis
 RICHARD H. WARREN—30. Non-operative treatment,
 practical considerations in the use of Miller Abbott
 tube
 L. S. McKEITHEN—330. Résumé, outline of treatment
 results.
 Staff—4. Operations

GEITO-URINARY SURGERY

- G. G. SMITH and associates—9. Operative and dry clinic
 G. G. SMITH and associates—9. Operations
 HOWARD I. SCHY—30. The solution of urinary calculi
 RICHARD CRUTE—50. Problems in the treatment of
 urinary calculi
 F. H. COLBY—5. Deep x-ray therapy in cancer of
 the bladder
 S. B. KIELLEY—40. Ureterostomy versus nephros-
 tomy

THORACIC SURGERY

- E. D. CRITCHFIELD and associates—Symposium. Sep-
 arative disease of the lung.

ORTHOPEDIC SURGERY

- M. N. SMITH PETERSON and associates—Operative and
 dry clinic

Friday

GENERAL SURGERY

- E. D. CRITCHFIELD and associates—9. Operative and dry
 clinic. Pancreatic tumors
 L. S. McKEITHEN and associates—Symposium. Peri-
 pheral vascular disease
 RICHARD H. WARREN—2. Fundamental considerations of
 thrombus formation, clinical manifestations, diagnosis
 and treatment
 H. H. FAXON—30. Pulmonary embolism, its relation
 to venous thrombosis
 RICHARD H. WARREN—45. Use of heparin in preven-
 tion of pulmonary emboli
 C. E. WELCH and C. E. McGARREY—3. Lymphography indi-
 cations, technique results.
 H. H. FAXON—35. Exploration and division of the
 femoral vein, indications and operative technique
 C. E. WELCH—335. Results, early and late, after divi-
 sion of the femoral vein.
 H. H. FAXON, C. E. WELCH, and RICHARD H. WARREN—
 4. Operations
 R. H. SMITHWICK and associates—Symposium. Surgery
 of hypertension, non-nephritic
 ROBERT S. P. LACK. Statement of the problem
 BENJAMIN CASTLEMAN. Renal pathology
 JOHN H. TALBOT. Renal physiology
 RICHARD CRUTE. Urological factors
 R. H. SMITHWICK. Modification of abnormal physiology
 by sympathectomy

OBSTETRICS AND GYNECOLOGY

- J. V. MILES and associates—9. Symposium. Gynecolog-
 ical problems
 J. V. MILES, LADONOV PAPERIS, and MARSHALL E.
 BARTLEY—9—30. Operations.
 J. V. MILES and associates—30. Discussion and
 demonstrations

ORTHOPEDIC SURGERY

- M. N. SMITH PETERSON and associates—9. Operative and
 dry clinic

PETER BENT BRIGHAM HOSPITAL

Tuesday

GENERAL SURGERY

- ELLIOTT C CUTLER and ROBERT E GROSS—9 Operations Ligation of patent ductus arteriosus, pericardiectomy
- ELLIOTT C CUTLER and associates—10 Symposium Surgery of the heart and blood vessels
- C SIDNEY BURWELL Forms of heart disease amenable to surgery
- SAMUEL A LEVINE Cardiac disease simulating surgical conditions of the abdomen and vice versa
- EUGENE C LEPFINGER Indications for surgery for patent ductus arteriosus
- ROBERT E GROSS Surgical treatment of patent ductus arteriosus
- ELLIOTT C CUTLER The technique of pericardiectomy
- MERRILL C SOSMAN The rôle of the roentgenologist in cardiac surgery
- JOHN HOMANS Peripheral vascular disease
- MARSHALL N FULTON Angiomas of skeletal muscle.
- DAVID CHEEVER—2 Dry clinic Surgical anatomy of the abdomen

Wednesday

GENERAL SURGERY

- ELLIOTT C CUTLER and ROBERT ZOLLINGER—9 Operations Gastric resections
- ELLIOTT C CUTLER and associates—10 Symposium Gastric and duodenal ulcer
- ELLIOTT C CUTLER Indications for surgery with gastric and duodenal ulcer
- EDWARD S EMERY, JR Medical management of bleeding peptic ulcer
- MERRILL C SOSMAN Significance of prepyloric ulcer
- HARRY A WARREN Duodenal diverticulum
- ROBERT ZOLLINGER Surgical treatment of severe duodenal ulcer
- ELLIOTT C CUTLER Results of acute gastroduodenal perforation
- CARL W WALTER—2 Symposium Aseptic technique

Thursday

GENERAL SURGERY

- FRANCIS C NEWTON and J ENGLEBERT DUNPHY—9 Operations Colon, rectum and anus
- ELLIOTT C CUTLER and associates—10 Symposium Colon, rectum and anus
- FRANCIS C NEWTON Experiences with cancer of the colon
- J ENGLEBERT DUNPHY Experiences with anterior resection for cancer of the rectosigmoid
- ANDREW W CONTRATTO and THOMAS B QUIGLEY Differential diagnosis of gastritis and gastro-enteritis from appendicitis
- MERRILL C SOSMAN The x ray and large bowel surgery
- EDWARD S EMERY, JR Medical diseases of the colon
- ELLIOTT C CUTLER Cicatrizing enteritis

GENITO-URINARY SURGERY

- WILLIAM C QUINBY and associates—2 Symposium
- J HARTWELL HARRISON The diagnosis and treatment of common injuries of the urinary tract
- GEORGE AUSTEN A correlation of the clinical aspects and pathology of the fused renal mass

- G PHILIP GRABFIELD Renal blood flow
- F ANTHONY SIMEONE Experimental hypertension
- WILLIAM C QUINBY A critical evaluation of prostatic surgery in recent years

Friday

GENERAL SURGERY

- ELLIOTT C CUTLER and ROBERT ZOLLINGER—9 Operations Cholecystectomy, choledochostomy
- ELLIOTT C CUTLER and associates—10 Symposium Surgical diseases of the biliary tract
- ELLIOTT C CUTLER Biliary calculus, technique of surgical therapy
- MERRILL C SOSMAN Upright films of the gall bladder as an aid in the diagnosis of cholelithiasis
- ROBERT ZOLLINGER Acute cholecystitis
- THOMAS B QUIGLEY Surgery of the biliary tract in the aged
- WILLIAM A DAVIS Clinical use of vitamin K in surgery of the biliary tract
- EDWARD S EMERY, JR Medical treatment after cholecystectomy
- ELLIOTT C CUTLER and associates—2 Symposium Surgical treatment of hyperthyroidism
- ELLIOTT C CUTLER The domain of thyroid surgery
- SAMUEL A LEVINE Pre-operative and postoperative treatment of severe thyrocardiacs
- MARSHALL N FULTON Recurrent hyperthyroidism
- J ENGLEBERT DUNPHY Use of silk in surgery of the thyroid
- HARRY B FRIEDGOOD Rôle of the pituitary hormone in thyrotoxicosis
- ELLIOTT C CUTLER Technique of thyroidectomy

BOSTON LYING-IN HOSPITAL

Tuesday

OBSTETRICS AND GYNECOLOGY

- Staff—10 Operative and dry clinic
- CHARLES A JANEWAY Treatment of puerperal sepsis with sulfanilamide and immune transfusions
- CLEMENT A SMITH Effect of various anesthetics as shown by blood gas determinations on mothers and their infants

Wednesday

OBSTETRICS AND GYNECOLOGY

- Staff—2 Dry clinic
- MFINOLPH V KAPPIUS The rôle of soft tissue x ray technique in the diagnosis of placenta previa
- ROBERT N RUTHERFORD Interpretation of bleeding in the first trimester of pregnancy as shown by endometrial biopsies
- ARTHUR T HERTIG Pathological ova, chief cause of spontaneous abortion
- ROBERT H BARKER Determination of cephalopelvic disproportion by the Thoms method of roentgenometry

Thursday

OBSTETRICS AND GYNECOLOGY

- Staff—10 Operative and dry clinic
- JOHN L NEWELL External cephalic version as prophylaxis against the fetal hazards of breech presentations
- DANIEL ABRAMSON End results of a conservative policy at delivery as shown in a study of postpartum patients

Friday

GENERAL SURGERY

Staff—1. Symposium

- C. G. SWED. Chemotherapy in general peritonitis.
 MAXWELL FINLAND. Chemotherapy in surgery.
 R. H. ALDRICH. The dynamical treatment of hernia with special reference to shock.
 H. G. DEXTER. "Z" plastics in hernia.

THORACIC SURGERY

Staff—9. Symposium

- J. W. STRICKER. Suppurative pericarditis, colored motion pictures, pericardectomy, result of modern method of treatment, lobectomy for bronchiectases.
 HORACE BURNETT. Methods and results of treatment of pulmonary tuberculosis.
 S. J. G. NOWAK. Experimental pulmonary embolus.
 DR. SEUTZ. Intratracheal anesthesia for thoracic surgery.

ORTHOPEDIC SURGERY

Staff—9. Symposium. Fractures of the hip

- NEWTON C. BROWDER. Intracapsular fractures of the hip.
 RUSSELL SULLIVAN. Hip fractures, cases of operative reduction and internal fixation.
 OTTO J. HERMANN. Painful un-united hip fractures.
 THOMAS H. PETERSON. Posterior fusion of the hip.
 A. A. THOMPSON. Stipped femoral epiphysis.
 JAMES W. SEVER. Presentation of cases.

FREE HOSPITAL FOR WOMEN

Tuesday

OBSTETRICS AND GYNECOLOGY

Staff—9. Symposium. Carcinoma of the cervix

- FRANK A. PENDERBTON—9. Operation. Radium application.
 ARTHUR T. HENSTON and F. CL. A. YOUNG—9-10. Drug deaths of early carcinoma.
 F. CL. A. YOUNG—10. Management of the uterological complications.
 GEORGE VAN S. SMITH—10-11. Results.

Wednesday

OBSTETRICS AND GYNECOLOGY

Staff—9. Symposium. Cancer of the endometrium

- FRANK A. PENDERBTON—9. Operation. Hysterectomy for carcinoma of endometrium.
 ARTHUR T. HENSTON—9. Pathology.
 GEORGE VAN S. SMITH—10. Results.

Thursday

OBSTETRICS AND GYNECOLOGY

- GEORGE VAN S. SMITH, JOSEY ROCK, and associates—9. Symposium. Fertility hormones in gynecology.

Friday

OBSTETRICS AND GYNECOLOGY

Staff—9. Symposium. Tumors of the ovary

- GEORGE VAN S. SMITH—9. Operation. Cancer of ovary.
 ARTHUR T. HENSTON—9. Pathology.
 FRANK A. PENDERBTON—10. Results.
 SIDNEY C. GRAVER—10. Kraurosis of the vulva.

humbomeral, sacro-iliac, myositis, myositis-fasciitis, industrial postural, mechanical findings.

THOMAS H. PETERSON. Coccygodynia, fracture of coccyx, conservatism vs. surgery in treatment.
 RUSSELL SULLIVAN. Anatomical abnormalities of the fifth lumbar vertebra and lumbosacral joint.
 G. KLEVORTE COCOT. Spondylo-listhesis. Pathology, diagnostic points, role of trauma in its production, and treatment.

A. P. ATKIN. Facial contractions.
 MARK H. ROOKES. Orthopedic aspect, intervertebral disc problem.
 P. F. BUTLER. Intervertebral disc problem, my aspect.
 DONALD ALVINO. Intervertebral disc problem, neurological aspect.

Staff—1. Symposium. Appendicitis, biliary system, and hernia.

P. S. FOWLE. Appendicitis and complications.
 G. W. PARKER. Incision for appendectomy in extreme obesity.
 T. W. WICKHAM. Analysis of 600 cholecystectomies.
 F. F. HENDERSON and JOHN McGOWAN. Operative biliary drainage for relief of jaundice—operative cure of gall bladder patient.
 J. J. HENDERSON. Familial hemolytic jaundice and splenectomy.

W. R. MORRISON. Stones of the hepatic ducts sub-diaphragmatic abscess.
 CHARLES LAMM. Peritoneoscopy with special reference to biliary disease.

ROBERT SMITH. Exteriorization of small intestines in strangulated hernia.

D. C. GOLDSWORTHY. Recurrent inguinal hernia.

Staff—2. Symposium. Anesthesia, large intestine, and other abdominal surgery.

T. W. WICKHAM. Foci of infection and ulcerative colitis.
 J. R. KINGTON. Surgery of large intestine.
 J. EDWARD F. TICE. Abdominoperineal resection of rectum for carcinoma with abscess formation.
 C. W. McCLELLAN. Sigmoidoscopy, kiodachrome pictures.
 FRANK MARVIN. Indications and contra indications for various anesthetics.

S. C. WYCKOFF. Spinal anesthesia.
 G. C. MOORE. Intravenous anesthesia.
 P. S. FOWLE. Ruptured corpus hemorrhagica.
 ALLEN D. VAIL. Calcified cyst of spleen.
 S. J. MADDOCK. High and low intestinal obstruction.
 ALLEN D. VAIL. Gun shot wounds of abdomen.
 HARRY B. LORER. Postoperative treatment.

GENITO-URINARY SURGERY

Staff—9. Symposium

H. H. HOWARD. Epidermoid carcinoma of the penis.
 GEORGE C. PRATHER. Stricture of the urethra.
 S. R. MUELLER. Newer concepts of urinary extravasation.
 G. D. ATKINSON. Scrotal plastics after idiopathic gangrene.
 W. H. HOLTHAM. Treatment of gonorrheal urethritis with sulfathiazole.
 J. A. SEER. Removal of calculi from lower ureter by the vaginal route—report of cases.
 F. G. SHERIDAN. Fracture of the penis, case report—anatomical study of remnants of prostatic tissue in the prostatic bed following coelocision.
 ARTHUR REID. Hemangioma of kidney—case report.

OPHTHALMOLOGY

JAMES J. REID and staff—9. Operations

ORTHOPEDIC SURGERY

G E HAGGART and J W TOUMEY, JR —9 Operations

OTORHINOLARYNGOLOGY

WALTER B HOOVER—9 Operations

F D LATHROP—1 30 Operations

WALTER B HOOVER—1 30 Dry clinic Local anesthesia in surgery of nose and throat, method used in tonsillectomy, adenoidectomy, lingual tonsillectomy, and excision of lateral pharyngeal bands, septum, sinus surgery including Caldwell Luc, external frontal, intranasal surgery, plastic procedures on external nose, disease of the esophagus, summary of symptoms, diagnosis and treatment of carcinoma, esophageal diverticulum, cardiospasm, esophagitis, ulcers, strictures of esophagus, and perforation, thyroid disease in the larynx, laryngeal paralysis

NEW ENGLAND BAPTIST HOSPITAL

Monday

GENERAL SURGERY

H D ADAMS and N W SWINTON—1 30 Operative clinic Thyroid, stomach, colon, rectum, and biliary tract

U H EVERSOLE, LEO V HAND, and M J NICHOLSON—1 30 Demonstrations Anesthesia

M H ROGERS Manipulation for chronic adhesive bursitis

Staff—2 Dry clinic

ALFRED HURWITZ Sulfanilamide vs zinc peroxide in the treatment of phagedenic ulcer

LOUIS ZITZLL The Miller Abbott tube

M D ALTSCHULE Effect of abdominal surgery on respiratory dynamics

H L BLUMGART The surgical risk in cardiac patients

JACOB FINE Treatment of intestinal distention by sulfaguanidine

ARNOLD STARR Sulfaguanidine for the sterilization of isolated loops of colon

GENITO-URINARY SURGERY

Staff—9 Dry clinic

I L PRIEN A new method for stone analysis

D B STEAFNS Parathyroid disease and urinary lithiasis

G C PRATHER Roentgenology of the kidney at operation

- U. H. EVERSOLE, LEO V. HARR, and M. J. NICHOLSON—*p.*
Anesthesia demonstrations. Regional, spinal, continuous
spinal, and general.
H. D. ADAMS and N. W. SWINNEY—*30.* Operative clinic
Thyroid, stomach, colon, rectum, and biliary tract.
U. H. EVERSOLE, LEO V. HARR, and M. J. NICHOLSON—
30. Demonstrations. Anesthetics.

GENITO-URINARY SURGERY

- E. L. EWERT and VERNOR S. DICK—*9.* Operations.

THORACIC SURGERY

- H. D. ADAMS—*30.* Operations

NEUROSURGERY

- J. L. POFFY—*9.* Operations.
GILBERT HORRAX—*30.* Operations.

ORTHOPEDIC SURGERY

- G. E. HAGGARD and J. W. TOURNEY, JR.—*9.* Operative
clinic.

OTO-RHINO-LARYNGOLOGY

- WALTER B. HOOVER—*9.* Operations.
F. D. LATIMER—*30.* Operations.

PALMER MEMORIAL HOSPITAL

Monday

GENERAL SURGERY

- Staff—Symposium. Carcinoma of the breast.
CLIFFORD C. F. VERNY—End-results of surgical treat-
ment.
L. S. MCKITTERICK—Interstitial irradiation treatment
of carcinoma of the breast with platinum radium
needles.
J. H. MARX—X-ray therapy of carcinoma of the
breast.
SARDEL VARNER—Relation between chronic cystic
mastitis and carcinoma of the breast.

Tuesday

OBSTETRICS AND GYNECOLOGY

- G. A. LELAND, JR. and C. J. SWAN—*1.* Symposium. Treat-
ment of carcinoma of the cervix.

Wednesday

GENERAL SURGERY

- Staff—Symposium. Carcinoma of the rectum and anus.
L. S. MCKITTERICK—Choice of operation in cases of
carcinoma of the rectum.
W. F. LEADREITER—Urological complications after
removal of the rectum.
L. S. MCKITTERICK—Treatment of carcinoma of the rectum
in poor risk cases with electrocoagulation and radium
implantation.
J. H. MARX—X-ray therapy of carcinoma of the rectum.
R. H. SWIFT—Carcinoma of the anal canal.
R. H. SWIFT or CLIFFORD C. FRANKLIN—End-results of
treatment of carcinoma of the rectum.

Friday

GENERAL SURGERY

- Staff—Symposium. Diabetic gangrene.

H. F. ROOT Medical aspects.

- L. S. MCKITTERICK—Principles of surgical treatment,
classification of lesions, conservative methods.
T. C. PRATT—Indications for and technique of major
amputation.
L. S. MCKITTERICK—Indications for and technique of
major amputation.
T. C. PRATT—End-result study of 100 patients after
supracondylar amputation for gangrene.
L. S. MCKITTERICK and T. C. PRATT—Operations
supracondylar amputations for gangrene.

CARNEY HOSPITAL

Tuesday

OBSTETRICS AND GYNECOLOGY

- LOUIS E. PRANSKY and associates—*9.* Operative clinic.
LOUIS E. PRANSKY and associates—*1.* Dry clinic.

Wednesday

GENERAL SURGERY

- WILLIAM E. BROWNE, W. R. MACAULEY, ROGER C.
GRAVER, and A. MCK. FRASER—*9.* Operations.
Staff—*1.* Dry clinic.

GENITO-URINARY SURGERY

- Staff—*1.* Dry clinic.

ORTHOPEDIC SURGERY

- Staff—*1.* Dry clinic.

Thursday

GENERAL SURGERY

- WILLIAM E. BROWNE, W. R. MACAULEY, ROGER C.
GRAVER, and A. MCK. FRASER—*9.* Operations.
Staff—*1.* Dry clinic.

GENITO-URINARY SURGERY

- Staff—*1.* Dry clinic.

ORTHOPEDIC SURGERY

- Staff—*1.* Dry clinic.

Friday

GENERAL SURGERY

- WILLIAM E. BROWNE, W. R. MACAULEY, ROGER C.
GRAVER, and A. MCK. FRASER—*9.* Operations.

ROBERT BRECK BRIGHAM HOSPITAL

Wednesday

ORTHOPEDIC SURGERY

- Staff—Symposium. End-results on rehabilitation of
chronic arthritis, prevention of deformities and early
rehabilitation, results in correction of flexion deformity
of knee, arthroplasty in upper extremity, open or
closed of arthritic disabilities of the foot.

Days to be Announced

ORTHOPEDIC SURGERY

- Staff—*9.* Operative clinic. Posterior capsuloplasty for
correction of flexion deformity of knee; arthroplasty of
elbow for ankylosis.

MASSACHUSETTS MEMORIAL HOSPITALS

Monday

THORACIC SURGERY

J W STRIEDER—2 Symposium

Tuesday

GENERAL SURGERY

HOWARD M CLUTE and staff—8 Operative clinic
 FRANK E BARTON—10 Symposium Management of blood bank
 PHILLIPS L BOYD—10 Dry clinic Lymphogranuloma venereum with rectal involvement
 THOMAS J ANGLE—2 Symposium Cancer of the breast
 FRANK E BARTON—2 Transfusion service

GENITO URINARY SURGERY

SAMUEL N VOSE and staff—9 Operative clinic

OTORHINOLARYNGOLOGY

HAROLD L BABCOCK and LEIGHTON F JOHNSON—2 Operative and dry clinic

Wednesday

GENERAL SURGERY

HOWARD M CLUTE and staff—8 Operative clinic
 GEORGE LEVENE and EGON G WISSING—9 30 Demonstration X ray examination of the rectum and sigmoid with special reference to the lateral view
 HOWARD M CLUTE—10 Symposium Stomach surgery
 FRANK E BARTON—2 Transfusion service

GENITO-URINARY SURGERY

SAMUEL N VOSE—9 Symposium Management of obstructing prostate

THORACIC SURGERY

J W STRIEDER—2 Operative and dry clinic

ORTHOPEDIC SURGERY

LOUIS G HOWARD and staff—9 Operative and dry clinic

OPHTHALMOLOGY

WILLIAM D ROWLAND—9.30 Dry clinic

OTORHINOLARYNGOLOGY

LEIGHTON F JOHNSON—2 Dry clinic Mediastinitis, 3 cases, 2 cures (with Howard M Clute), endaural repair of postauricular fistula, 3 cases, osteomyelitis of frontal bone, Lempert's operation, endaural fenestration for otosclerosis

Thursday

GENERAL SURGERY

HOWARD M CLUTE and staff—8 Operative clinic
 MILO C GREEN, CHESTER S KEEFER, HOWARD M CLUTE, HOLLIS L ALBRIGHT, SAMUEL N VOSE, and LEIGHTON F JOHNSON—10 Use of sulfonamide group in surgery
 ARTHUR L HANRAHAN—10 Operative and dry clinic Treatment of varicose veins and ulcers

OBSTETRICS AND GYNECOLOGY

C WESLEY SEWALL and staff—8 Operative and dry clinic, ward walk

C WESLEY SEWALL and staff—2 Symposium Obstetrical
 JOHN J ELLIOTT A ten year study of bleeding in the third trimester of pregnancy
 OWEN C MULLANEY Prenatal and postnatal care
 JOHN C V FISHER. A ten-year survey of cesarean section
 MAX DAVIS Physiology and clinical application of testosterone
 KENNETH W SEWALL A twenty-year survey of eclampsia
 HERMAN C PETTERSON Modern care of the newborn

ORTHOPEDIC SURGERY

LOUIS G HOWARD, ALBERT B FERGUSON, and associates—9 Discussion of bone tumors

OPHTHALMOLOGY

WILLIAM D ROWLAND and RALPH H HOPKINS—2 Operative clinic

Friday

GENERAL SURGERY

HOWARD M CLUTE and staff—9 Operative clinic

GENITO-URINARY SURGERY

SAMUEL N VOSE—9 Operative and dry clinic

UNITED STATES MARINE HOSPITAL

Tuesday

GENERAL SURGERY

R L WAUGH and staff—8 Operative clinic Hernioplasty, indirect, direct, and femoral, appendectomy, ligation of saphenous vein and hemorrhoidectomy
 R L WAUGH and staff—11 Dry clinic Appendicitis, intestinal parasites, and terminal ileitis

FRACTURES AND OTHER TRAUMAS

R L WAUGH and staff—8 Operative clinic Internal derangement of knee joint, bunion, closed treatment, double pin method, fracture both bones of leg, open treatment, vitalium plate, both bones forearm
 R L WAUGH and staff—1 Dry clinic Skeletal traction and countertraction methods applicable to ordinary extension splints in the treatment of fractures of lower extremity, vitalium in fractures, injuries of the wrist and rupture of biceps brachii

Friday

GENERAL SURGERY

R L WAUGH and staff—9 Operative clinic Hernioplasty, indirect, direct and femoral, appendectomy, ligation of saphenous vein and hemorrhoidectomy
 R L WAUGH and staff—11 Dry clinic Appendicitis, intestinal parasites, and terminal ileitis

FRACTURES AND OTHER TRAUMAS

R L WAUGH and staff—9 Operative clinic Internal derangement of knee joint, bunion, closed treatment, double pin method, fracture both bones of leg, open treatment, vitalium plate, both bones forearm
 R L WAUGH and staff—1 Dry clinic Skeletal traction and countertraction methods applicable to ordinary extension splints in the treatment of fractures of lower extremity, vitalium in fractures, injuries of the wrist and rupture of biceps brachii.

Daily—9 to 5

SCIENTIFIC EXHIBIT

- JOSEPH GOODMAN. Pathogenic fungi in foot infections.
 J. F. FRIEDMAN. Malignant disease before and after treatment by radiation.
 ABRAHAM RUDY and S. R. MYLLER. Neurogenic bladder in diabetes mellitus.
 JULIUS LOMAX. Action of antiseptic drugs on the gastro-intestinal and genito-urinary tracts.
 S. A. ROSSIE. Uretrography and cystography.
 W. S. ALTMAN and A. L. HERN. Nov. Cholangiography.
 L. NATRIA and Dr. TROVAT. Cysts and tumors of mouth and jaw.
 JULIUS LOMAX. Cerebral arteriography.

FAULKNER HOSPITAL

Wednesday

GENERAL SURGERY

- E. L. YOCUM, A. R. KIMPTON, F. G. BALCH, H. K. SOWLES, R. F. SEELDON, E. E. O'NEIL, R. S. TITUS, and R. J. HEFFERMAN—8. Operative clinic.
 S. C. WOODY—8. Anesthetics exhibits.
 J. B. HALLAM—8. Pathological specimens, slides.
 E. L. YOCUM, F. G. BALCH, Dr. O'NEIL, A. R. KIMPTON, H. K. SOWLES, R. F. SEELDON, R. J. HEFFERMAN, R. S. TITUS, Dr. STRAUSS, Dr. MALONEY and E. E. O'NEIL—2. Dry clinic.
 HARVEY MORRISON—2. X ray demonstrations.

Thursday

ORTHOPEDIC SURGERY

- E. G. BRACKETT, H. C. MARBLE, O. M. MORRISON, J. D. ADAMS, and OTTO J. HERMANN—8. Operative clinic.
 HARVEY MORRISON—8. X ray demonstrations.
 E. G. BRACKETT, A. P. ATKIN, J. L. DOWNEY, H. C. MARBLE, OTTO J. HERMANN, HARVEY MORRISON, J. D. ADAMS, and H. L. JORDAN—2. Dry clinic.
 JOHN HOSKINS, C. G. MYNTER, R. H. SMITH, Dr. WHITE, E. E. O'NEIL, H. C. MARBLE, and J. S. HODGSON—4. Symposia. Cannula.

BEVERLY HOSPITAL

Thursday

GENERAL SURGERY

- Staff—9. Demonstration of newly constructed operating room with elimination of explosion and fire hazards.

FRACTURES AND OTHER TRAUMAS

- PET. P. JOHNSON, JOHN D. ADAMS, and RICHARD E. ALT—Dry clinic. Discussion by CLAU. RAY MITCHELL, ROBERT H. KENNEDY and I. EDWARD W. BANCROFT.

MALDEN HOSPITAL

Friday

GENERAL SURGERY

- I. J. WALLER and staff—9. Operations (Gastro-intestinal).
 I. J. WALLER and staff—2. Dry clinic.

OBSTETRICS AND GYNECOLOGY

- NICHOLAS A. GALLAGHER—9. Operations Gynecological.

- B. E. GREENBERG. Use of cholinergic and adrenergic medication for ureteral stone passage.
 H. A. KOVTOFF. Hospital statistics on urinary lithiasis.
 J. H. LIPTON. Clearance of infection in stone cases after operation.
 D. B. STRAUSS. Diagnosis of calyceal calcifications.
 H. A. KOVTOFF. Renal tumor statistics of the hospital.
 Demonstration. Surgical specimens of renal tumors with pyelographic and microscopic data.
 E. G. CHAFFIN—Operation. Excision of renal tumor.
 Staff—Dry clinic.
 M. L. BROOKE. Fractional pyelography.
 J. H. LIPTON. Sulfonamide drugs in surgical wounds and postoperative infections.
 B. E. GREENBERG. Methylene blue treatment for tuberculous of the bladder.
 L. L. PIERCE. Renal injury from sulfathiazole and sulfapyridine, nature of the lesion.
 D. B. STRAUSS. Undescended testicle age groups.
 M. L. BROOKE. Urological study of excretory cases.
 Dr. FRIEDMAN. Denervation of the kidney—end-results of 300 cases.
 B. E. GREENBERG. Organization and function of the urinary clinic.
 NATHAN CH. YET. Hypertensive disease in urology.

Friday

GENERAL SURGERY

- Staff—9. Dry clinic.
 C. G. MYNTER. Results of surgery of colon neoplasms classified according to extent of lesion.
 L. E. BARROW. Pitfalls in diagnosis of carcinoma of stomach, observations in 300 cases.
 C. G. MYNTER. Results of surgery of gastric neoplasms classified according to extent of lesion.
 I. T. NATHANSON. Surgical management of lymph nodes in cancer surgery.
 K. PRIMER. Differential diagnosis of gastric ulcer by radiography.
 JACOB FIDEL—9. Operation. Colon resection.
 C. G. MYNTER—9. Operation. Gastric resection.
 Staff—2. Dry clinic.
 A. M. SELIGMAN. Vitamin K in treatment of hypoprothrombinemia in infants.
 J. J. MICHAELS and Miss E. CORNELL. Psychiatric conditions in surgical patients.
 B. RUDINMAN. The surgical treatment of angina pectoris.
 S. A. ROSSIE. Diagnosis of non-calcified dermoid cysts.
 A. M. SELIGMAN. Cardiovascular agents.
 H. L. CANNY. Surgical management of pulmonary tuberculosis.
 ALFRED THURM. Thoracic esophageal diverticulum.

OTORHINOLARYNGOLOGY

- Staff—9. Dry clinic.
 SAMUEL CLINE. Tuberculous laryngitis.
 OSCAR HIRSCH. Sphenoid approach through suboccipital septum.
 A. J. GORDON. Lempert's simple and radical mastoid operations.
 S. W. GARDNER. Transseptal approach for dacryocystitis.
 H. F. FRIEDMAN. Radiation for carcinoma of larynx by the Coard method.
 BENJAMIN RUDINMAN. Cervicofacial abscess thrombosis.
 LOUIS M. FRIEDMAN. Coard radiation therapy for carcinoma of larynx, end results. Lempert technique for simple and radical mastoidectomy.
 LOUIS M. FRIEDMAN. Operation Lempert for mastoiditis.

M G KARP—10.45 Fractures about the elbow in childhood.
Staff—11 15 Congenital malformations

Daily—2 to 5

SCIENTIFIC EXHIBIT

Exhibit of pathological specimens, x-rays, photographs, and charts from the surgical, orthopedic and neuro surgical services

NEW ENGLAND MEDICAL CENTER

JOSEPH H PRATT DIAGNOSTIC HOSPITAL

Monday

GENERAL SURGERY

Staff—2 Dry clinic
JOSEPH H PRATT Surgical problem in pancreatic disease.
WILLIAM DAMESHEK. Indications for splenectomy, case reports
JOHN D ADAMS Orthopedic subject, to be announced
WALTER E GARREY Peritoneoscopy

Tuesday

GENERAL SURGERY

Staff—2 Dry clinic
C H LAWRENCE Masculinizing tumors
R H BETTS Subject to be announced
WILLIAM M SHEDDEN Subject to be announced
EDWARD T WHITNEY Subject to be announced

Wednesday

GENERAL SURGERY

Staff—2 Dry clinic
RICHARD H. OVERHOLT Operability of primary carcinoma of the lung
L E PHANEUF Subject to be announced
S J THANNHAUSER. Liver function tests as an aid to gall bladder surgery
H E MACMAHON Subject to be announced

BOSTON FLOATING HOSPITAL

Thursday

GENERAL SURGERY

RICHARD WAGNER and W S LEVENSON—2 Endocrinology and surgery
DR. McDONALD and R G FREEMAN—2 Appraisal of the host, nutrition, personality
DR. McDONALD, W S LEVENSON, DR. WERTHESEN, and H E MACMAHON—2 Adrenal dysfunction

GENITO-URINARY SURGERY

H.A CHAMBERLIN—2 Genito-urinary surgery in children

THORACIC SURGERY

RICHARD H OVERHOLT, R. H BETTS, and DR. WELLER—2 Tidal drainage, lung abscess

OTORHINOLARYNGOLOGY

W A. MACCOLL—2 Tonsils and adenoids, indications for removal.

BOSTON DISPENSARY—PRATT CLINIC

Days to be Announced

OTORHINOLARYNGOLOGY

GEORGE KELEMEN Pathogenesis of traumatic cholesteatoma, lantern slides, surgery of the tonsil after middle life, pathways of infection in the ear, lantern slides
PHILIP E MELTZER. Surgical anatomy of the temporal bone

UNITED STATES NAVAL HOSPITAL

Tuesday

GENERAL SURGERY

J J A McMULLIN and staff—9 Operations
JAMES J REGAN—9 Demonstrations of technique used in flight physical examinations, with discussion of United States Naval requirements

OTORHINOLARYNGOLOGY

CHARLES H ALLMAN—9 Dry clinic Bronchoscopy for bronchiectasis, pulmonary abscess and postoperative atelectasis, synopsis of case histories and accomplishments

Wednesday

GENERAL SURGERY

LAWRENCE J MCCARTHY and staff—9 Operations
THOMAS H PETERSON—9 Shoulder injuries, discussion of case histories, x-ray findings
WALTER E GARREY—9 Dry clinic Circulatory diseases of the extremities, case histories

Thursday

GENERAL SURGERY

WALTER E GARREY and staff—9 Operations
LAWRENCE J MCCARTHY and WALTER E GARREY—9 Gastro intestinal clinic Partial gastrectomy for pyloric obstruction with a synopsis of case histories

GENITO-URINARY SURGERY

E ROSS MINTZ—9 Dry clinic Presentation of urological cases with histories and x-ray findings

Friday

GENERAL SURGERY

THOMAS H PETERSON—9 Operations

OBSTETRICS AND GYNECOLOGY

JOSEPH B DOYLE—10 Colored moving pictures of spinal anesthesia in obstetrics, discussion of case histories

COLLIS P HUNTINGTON MEMORIAL HOSPITAL

Monday

GENERAL SURGERY

Staff—2 15 Dry clinic
JOSEPH C AUB Recent advances in our knowledge of bone diseases
CHANNING C SIMMONS Malignant tumors of bone

MASSACHUSETTS EYE AND EAR
INFIRMARY

Monday

OPHTHALMOLOGY

F. H. VERBOEFF and WILLIAM P. BEETHAM—5. Dry clinic. Cataract surgery.

Tuesday

OPHTHALMOLOGY

PAUL A. CHANDLER, FRED S. THORNT, T. ROY GUNDEY and PAUL G. HARRIS—9. Operations.

PAUL A. CHANDLER—5. Glaucoma, indications for operation.

SAMUEL T. CLARKE—5. Goniotomy, medical treatment.

Wednesday

OPHTHALMOLOGY

WILLIAM P. BEETHAM, SAMUEL H. WILKINS, BRENDAN D. LEANEY and D. TO G. COOGE—9. Operations.

E. B. DUNPHY—15. Strabismus, orthoptic training.

VIRGIL G. CASTER—5. Strabismus, operative treatment.

Thursday

OPHTHALMOLOGY

EDWIN B. GOODALL, RALPH H. RUGGER, MERRILL J. KING, and HERMA GROSSMAN—9. Operations.

MERRILL J. KING—15. Dry clinic. Retinal separation.

BRENDAN D. LEANEY—15. Dry clinic. Keratoplasty.

Friday

OPHTHALMOLOGY

BENJAMIN SACHS and JOHN G. JENNINGS—9. Operations.

Staff—9. Demonstrations.

WILLIAM P. BEETHAM. Slit Lamp.

GARRETT L. SULLIVAN. Perimetry.

VIRGIL G. CASTER. Neuro-ophthalmology.

SAMUEL T. CLARKE. Gonioscopy.

T. L. TERRY—215. Dry clinic and lantern demonstrations of pathological specimens.

V. H. KALANJIAN—215. Ophthalmoplastic surgery.

Days to be Announced

OTORHINOLARYNGOLOGY

A. S. MACMILLAN. Interpretation of x-rays and mastoid x-rays.

L. G. RICHARDS. Bronchoscopy problems.

C. T. PORTER. Orbital abscess, diagnosis and treatment.

L. A. SCHALL. Cancer of the nose and sinuses. Laryngeal cancer.

G. B. FRIED. Osteomyelitis of the frontal bone.

H. G. TOLBY. Allergy otolaryngological considerations.

P. E. METZGER and C. I. JONASOFF. The laryngostomy operation.

RENE GILDER. The deaf child.

V. H. KALANJIAN. Rhinoplastic surgery.

PHILIP MYERS. Labyrinthectomy, review of cases.

C. M. KOS. Meningitis, review of cases.

SCIENTIFIC EXHIBIT

T. L. TERRY. Pathological laboratory open for inspection.

D. TO G. COOGE. How laboratory and library open for inspection.

CHILDREN'S HOSPITAL

Tuesday

GENERAL SURGERY

W. E. LADD and associates—10. Dry clinic. Surgical diseases of the gastro-intestinal tract in childhood. Atresia, stenosis, and malrotation. Pyloric stenosis. Intussusception, appendicitis, followed by questions and discussion.

GENITO-URINARY SURGERY

W. E. LADD and associates—9. Dry clinic. Surgical diseases of the genito-urinary tract in infancy and childhood. Embryoma, malformations, ectropion and epispadias, followed by questions and discussion.

ORTHOPEDIC SURGERY

F. R. OWEN and associates—9. Operations.

Wednesday

GENERAL SURGERY

W. E. LADD and associates—9. Operations.

ORTHOPEDIC SURGERY

F. R. OWEN and associates—9. Dry clinic.

W. A. ELLISTON—9. Study in bone growth and resorption of the epiphyseal plate.

L. M. MCDERMOTT—9. Equalization of leg length by leg lengthening.

P. W. H. GIESSENGER—9. Tuberculosis of bone.

A. H. BREWSTER—30. Arthrodesis of the foot in spastic paralysis.

Staff—9. Synostosis on infantile paralysis, operative treatment.

Thursday

GENERAL SURGERY

W. E. LADD and associates—9. Dry clinic. Plastic surgery in childhood. Harlip and cleft palate. Burns, early and late treatment. Hands, syndactylism and polydactylism. Plastic for malformations about nose, followed by questions and discussion.

THORACIC SURGERY

W. E. LADD and associates—30. Dry clinic. Chronic suppuration, heart, patent ductus arteriosus. Questions and discussion.

NEUROSURGERY

W. E. LADD and associates—30. Dry clinic.

ORTHOPEDIC SURGERY

F. R. OWEN and associates—9. Operations.

Friday

GENERAL SURGERY

W. E. LADD and associates—9. Operations.

ORTHOPEDIC SURGERY

F. R. OWEN and associates—9. Dry clinic.

M. G. KATHLEFF—9. Early treatment of club-foot.

R. H. MORSE—9. Treatment of the difficult club-foot.

F. R. OWEN—30. Treatment of congenital elevation of the scapula.

DR. GREEN—30. Osteochondritis dissecans.
